Few cities are more fortunate in the quantity and quality of their water supply than are New York and Brooklyn. The Croton water is brought to the city of New York by an aqueduct 45 miles long. Where the water enters the aqueduct a dam, 230 feet wide and 45 feet high, was erected in the Croton River, by which the Croton Lake was formed. This serves as a great reservoir, or sedimentary basin. The purity of the Croton water is remarkable; the following table shows the quan-

titles of different substances obtained from one United States' gallon of 231 cubic inches:—

	Grains.
Soda	0'326
Potassa	0'097
Lime	0'988
Magnesia	0'524
Chlorine	0'243
Sulphuric acid	0'322
Silica	0'621
Alumina and oxide of iron	trace
Carbonic acid (calculated)	2'604
Water in bicarbonates (calculated)	0'532
Organic and volatile matter	0'670
Total	6'927
Less oxygen, equivalent to the chlorine	0'054

6'873

These acids and bases are probably combined in the water as follows:—

Chloride of sodium	0'402
Sulphate of potassa	0'179
Sulphate of soda	0'260
Sulphate of lime	0'158
Bicarbonate of lime (CaO,HO,2CO ₂)	2'670
Bicarbonate of magnesia (MgO,HO,2CO ₂)	1'913
Silica	0'621
Alumina and oxide of iron	trace
Organic matter	0'670

Total 6'873

On evaporating a gallon of this water a residue of only 4'78 grains is obtained, the bicarbonates of lime and magnesia being left as simple carbonates.

The following tabular statement shows how favourably the Croton compares with the waters supplied to other cities:—

Impurities contained in One Gallon of 231 cubic inches, expressed in grains.

City.	Source.	Inorganic Matter.	Organic and Volatile Matter.	Total Solids.
New York	Croton, average for 13 weeks, 1867 (C. F. Chandler)	3'90	0'66	4'56
New York	Croton, average for 3 months, 1868 (C. F. Chandler)	3'31	1'14	4'45
New York	Croton, average for 6 months, 1869 (C. F. Chandler)	4'11	0'67	4'78
New York	Well west of Central Park (C. F. Chandler)	38'95	4'35	43'30
Philadelphia	Delaware (H. Wurtz)	2'93	0'55	3'48
London	Thames (Dr. H. Letheby)	15'55	0'83	16'38
London	Well, Leadenhall Street (Dr. H. Letheby)	90'38	9'39	99'77
Dublin	Lough Vartry, new supply (Apjohn and others)	1'77	1'34	3'11
Paris	Seine, above the City (Bussey, Wurtz, and Ville)	7'83	1'00	8'83
Amsterdam	River Vecht (V. Baumhauer and V. Moorsel)	14'45	2'13	16'58
Amsterdam	Deep well at the Keisersgracht	64'55	4'38	68'93

CORRESPONDENCE.

THE ATOMIC THEORY.

To the Editor of the Chemical News.

SIR,—We have heard much of late respecting the uselessness to the chemist of Dalton's theory. No believer in progression considers that the conception it affords of the constitution of matter is an absolutely true one. For upwards of half a century the theory has done incalculable service to chemistry, and remains still the guiding-star of that science.

Every worker would hail with joy an attack on this simple but noble creation of a great mind, were the assailants armed with that resistless weapon—*experiment*. Phlogiston fell, as other theories have fallen, not by words, but by the sheer power of experiment. The anti-atomists should, therefore, follow the example set by Lavoisier, and attack what they consider so useless for mentally connecting experimental facts, and so injurious to scientific thought and progress, by the only means that can avail.—I am, &c.,

ALFRED TRIBE.

May 27, 1872.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Seances de l'Académie des Sciences, April 22, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Method of Quantitatively Estimating Copper by means of Solution of Cyanide of Potassium.—De Lafolle.—Reserved for full translation.

Action of Sulphuric Ether on Iodides.—E. Ferrière.—When to a solution of any iodide in water there is first added some starch solution, and this mixture shaken up with sulphuric ether, the following phenomena are observed:—If the solution of the iodide is somewhat concentrated, a portion of iodine is set free, and the starch is coloured blue; if the solution is weak, this colouration only sets in after some three hours; if the solution is very dilute, the blue colouration only appears after some two or three days. When the blue-coloured starch is separated by filtration, and there is added to the filtrate another dose of ether, the blue colouration again appears, all the iodine being at last driven from its combination; chlorides and bromides are not thus acted upon. The author attributes this decomposition to the slow but continuous formation of an unstable iodhydric ether, (C₂H₅I), but the experimental proof of that reaction has not been found by him.

Synthesis of Orcin.—G. Vogt and A. Henniger.—By heating chlorated toluen, C₇H₇Cl, upon a water-bath, there are obtained two chloro-cresyl-sulphuric acids, C₇H₆(Cl,SO₂H), which are converted into two isomeric acid baryta salts:—

The first-named of these salts, which is soluble in cold water, crystal line, and also soluble in boiling alcohol, yields orcin when fused with caustic potassa, although it might have been supposed that a diphenol of the formula—

This reaction is elucidated by the following formula:—

The orcin thus synthetically formed is in all respects identical with that obtained from lichens, but the process of preparing it is not industrially applicable.

Researches on the Physiological Action of the Different Opium Alkaloids.—Dr. Rabuteau.—This lengthy memoir contains the results of some very important experiments, made with the view to elucidate the action of the different opium alkaloids upon the human system.

This number also contains a series of important papers relating to astronomy, meteorology, geology, and zoology.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 7, 1872.

This number contains the following original papers and memoirs:—**Specific Heat of Carbon.**—H. F. Weber.—Notwithstanding the high scientific value of this exhaustive memoir, its contents are not well suited for abstraction.

* This salt is formed from the baryta salt by double decomposition with sulphate of potassa.

Behaviour of the so-called Sulphuric Acid Chamber Crystals towards Water.—C. Ramsberg.—In the introduction to this lengthy memoir, the author first reviews the conditions of the formation of the compound alluded to, which may be formed (1) by the action of sulphuric acid upon nitrous acid; (2) by the action of sulphuric acid on dioxide of nitrogen (so-called hyponitric acid); (3) by the action of sulphurous acid upon dioxide of nitrogen in the presence of too small a quantity of water. This latter is the mode of formation in the sulphuric acid chambers if sufficient water (steam) is not present. The author then quotes the results of the analysis of the crystals as found by Clément and Desormes, Gautier de Claubry, Weber, Weltzien, and others. The formula of the lead chamber crystals is—

In the continuation of this memoir, the author treats at great length on the action of water upon the body just alluded to; it appears that in 100 parts of the crystals there are contained 6.38 per cent of N_2O_5 = N, 1.65, and 20.47 per cent N_2O_5 = N, 7.54; N = 9.19 per cent; to this quantity of N has to be added 2.57 N which are set free in the shape of NO, bringing the total amount of N up to 11.76 per cent. By becoming decomposed by water, the chamber crystals yield 22 per cent of oxide of nitrogen, 14 per cent of nitric acid, and 64 per cent of nitrous acid.

Estimation of Uric Acid.—H. Schwanert.—The main gist of this physiologico-chemical paper is that hydrochloric acid fails to precipitate uric acid from urine completely, so that, upon 100 c.c. of fluid (urine) treated with hydrochloric acid, a quantity of 0.0045 grm. of uric acid remains in solution, and has, of course, to be added to the quantity of uric acid found.

Short Communication on Naphthalin-Carboxyl-Acid-Amide.—P. v. Rakowski.—The author states that, while preparing naphthol acid according to Merz's method, by boiling naphthalin-cyan with alcoholic potassa solution, he obtained, by exhausting the residue with water, a compound (not naphthalin, as stated by Merz) which, on being submitted to elementary analysis, led to the formula $\text{C}_{11}\text{H}_9\text{NO}$ —that is to say, naphthalin-carboxyl-acid-amide; constitutional formula, $\text{C}_{10}\text{H}_7\text{CONH}_2$.

Silico-Heptyl Series.—A. Ladenburg.—The continuation of a lengthy monograph on this subject.

Constitution of Benzol.—A. Ladenburg.—The contents of this paper are, notwithstanding the intrinsic merits, not well suited for useful abstraction.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 232, April, 1872.

This number does not contain any original papers relating to chemistry.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, March 14, 1872.

Alloy which may serve to Unite Iron or Steel to Brass.—C. Mène.—The alloy consists of 3 parts of tin, 39.5 of copper, and 7 of zinc, which latter, since some of it is volatilised by the smelting together of the metals, may be increased to 10 parts; this alloy may serve to unite (solder together) copper or brass to iron or steel.

Les Mondes, April 25, 1872.

Bibliography.—Under this heading we quote the titles of the following works, which are highly spoken of in the above-quoted periodical:—"Histoire de l'Economie Politique des Anciens Peuples de l'Inde, de l'Egypte, de la Judée, et de la Grèce," par M. du Mesnil-Marié; 2 vols.; Paris: H. Plon, 1872. "Cours Élémentaire de Géologie Appliquée, Lithologie Pratique ou Etude Générale et Particulière des Roches," par M. Stanislas Meunier; Paris: Dunod, 1872.

General Theory of Chemical Action.—Dr. E. J. Mauméné.—The first instalment of a series of papers on this subject, elucidated by woodcuts and a series of algebraical formulæ.

Annalen der Chemie und Pharmacie, May, 1872.

This number contains the following original memoirs and papers:—

Butyric Acids of various Origin.—C. Grünsweig.—This very lengthy monograph contains the following sections:—Introduction, a concisely written and complete review of all that has been done by different authors in this direction; normal butyric acid; oxidation of normal butyric acid; salts of the normal butyric acid, viz., of silver, calcium, strontium, and zinc; normal butyric acid isobutyrate (isobutyrate); isobutyric acid; oxidation of isobutyric acid; salts of this acid, viz., of silver, calcium, strontium, and zinc; isobutyric acid isobutyrate; butyric acid from butter; butyric acid from conline; butyric acid from St. John's bread, carob-tree (*Ceratonia siliqua*).

Pollen, and on the Formation of Wax.—W. von Schneider.—The first instalment of an exhaustive monograph, the contents of which are, notwithstanding their high scientific value, not suited for abstraction.

Studies on the Combinations of the Camphor Group.—J. Kachler.—The second instalment of a lengthy monograph on this subject divided into the following sections:—Campholic acid, $\text{C}_{10}\text{H}_{14}\text{O}_2$; salts of this acid, viz., of potassa, soda, ammonia, lime, baryta, magnesia, zinc, copper, silver; campholic acid and bromine; campholic acid and phosphorochloride; dry distillation of the salts of campholic acid; campanic acid.

Azo Compounds of Resorcin.—P. Weselsky.—This memoir, elucidated by a large number of complex and lengthy formulæ, is divided into the following chapters:—Introduction; diazo-resorufin; hydrochlorate of hydro-diazo-resorufin; resorcin-tetra-azo compounds; nitrate of tetra-azo-resorufin; nitrate of dihydro-tetra-azo-resorcin; hydrochlorate of hydro-amido-tetra-azo-resorufin; hydro-imido-tetra-azo-resorufin; diazo-resorcin and acetyl-chloride.

On Dextronic Acid.—J. Habermann.—The acid just named is formed from dextrine, in the same manner as lactic acid is formed from sugar of milk, viz., by heating in a water-bath a mixture of 50 grms. of dextrine, 300 c.c., and 40 grms. of bromine, the mixture being poured into strongly-made bottles, champagne wine bottles answer the purpose best,—the fluid is first treated with oxide of silver, next with hydro-sulphuric acid, and the free dextronic acid then converted into a lime, and afterwards into a lead salt, from which at last the acid is set free; the free acid is very similar to gluconic acid, but exhibits a slight difference from the latter as regards its behaviour in the polarisation apparatus; dextronate of lime, $\text{C}_6\text{H}_{11}\text{CaO}_7 + \frac{1}{2}\text{H}_2\text{O}$, contains water of crystallisation driven off at 120° .

Products of Distillation of Sugar mixed with Lime.—R. Benedikt.—This paper treats on the substances obtained by the dry distillation of a mixture of lime and sugar (3 parts of lime to 1 of sugar). The author states that metaceton and isophoron are the chief fluid products of this operation, but a large quantity of gases are simultaneously formed.

Some of the Products of the Condensation of Aldehyde.—A. Kekulé.—The fourth portion of this monograph, treating on the condensation of aldehyde with the taking up (*Aufnahme*) of hydrogen.

On Rufoiline.—C. Liebermann and C. Chojnacki.—After first referring at some length to the researches of Anderson, Matthiessen, Foster, and others on this subject, the authors treat on the preparation of rufoiline, a colouring matter, $\text{C}_{11}\text{H}_9\text{O}_5$, which they state to be very closely allied to the madder pigments; while, moreover, rufoiline, treated with zinc dust, yields anthracen. The close alliance between rufoiline and the anthracen pigments is elucidated in the following manner:— $\text{C}_{11}\text{H}_9\text{O}_5$, monoxo-anthrachinon; $\text{C}_{14}\text{H}_9\text{O}_4$, alizarine; $\text{C}_{11}\text{H}_9\text{O}_5$, purpurine; $\text{C}_{14}\text{H}_9\text{O}_6$, rufoiline (pseudopurpurine?); $\text{C}_{14}\text{H}_9\text{O}_6$, rufigallic acid.

On Naphthazarine.—C. Liebermann.—Notwithstanding the high scientific value of this memoir, its contents are not well suited for any useful abstraction, an observation also bearing upon the following memoir:—

Aromatic Glycolic Acid.—W. Dittmar and A. Kekulé.

Some Combinations of Tungsten (Wolfram).—Dr. H. E. Roscoe.—This essay is divided into the following sections:—Preparation of metallic tungsten; chlorides of tungsten—viz., hexachloride, pentachloride, tetrachloride, dichloride; oxychlorides; bromides; reduction of the pentabromide in hydrogen; oxybromides—viz., monoxobromide, dioxobromide; iodide; atomic weight of tungsten—(a) by reduction of the trioxide, (b) by analysis of the hexachloride.

Salt (Chloride of Sodium) contained in the Extract of Meat.—Dr. J. Baron von Liebig.—The eminent *savant* has written this paper with the view to refute the allegation made by a Dr. Godefroy, who appears to have published, in an Austrian scientific paper, a statement to the effect that Liebig's extract of meat should contain a per cent of chloride of sodium, purposely added as a fraud. The author refers Dr. G. to his (Liebig's) essays published in this periodical some twenty years ago, "On the Constituents of the Fluids contained in Meat," and emphatically denies that at Fra Bentos, where the extract of meat is made, any common salt is added to it. Chloride of potassium is largely contained in the extract.

Oxygen-Containing Ethyl Compounds.—E. Erlenmeyer.—This essay is divided into the following chapters:—Experiments on the formation of alcohol from ether, and of ether from alcohol, under the influence of dilute sulphuric acid and a higher temperature; formation of ether from alcohol under the influence of sulphuric acid, ethyl-ester (ethyl-ester) and ethyl-sulphuric acid; sulphuric acid ethylester; alcohol and ethyl-sulphuric acid; on Gerhardt's parathionic acid.

Dicyanacetic Acid.—D. Amato.—This paper treats at length on the results of a series of experiments made with the view of trying to bind three carboxyles (CO.OH) to the same carbon atom. The author describes, however, mainly the action of cyanide of potassium upon dichloroacetic ether.

La Revue Scientifique de la France et de l'Etranger, April 27, 1872.

This number does not contain any original papers on chemistry, but we quote the titles of the following interesting papers:—

The Resources, Soil, Climate, Population, Agriculture, Industry, and Commerce of the Alsace.—Ch. Grad.

Continuation of the Lectures on Animal Heat; Temperature of Arterial and Venous Blood.—C. Bernard.—Illustrated by woodcuts.

NOTES AND QUERIES.

Waste of Sulphur in the Cornish Tin Mines.—The writers of letters to Dr. Taylor with reference to the article as above, which appeared in last week's number, will oblige by sending their addresses, as their letters have been lost in forwarding to the post.—W. H. TAYLER, M.D., Tudor House, Anerley, Surrey.

Chinese Cement.—Some time since there appeared a notice of a Chinese Cement (Schio Liao), consisting of 3 parts of blood and 4 of lime, with a little alum. I have tried it, but not with the success I expected. I have used sheep's blood. Finding in Cooley's "Receipts" what is called "coppersmith's cement," made from bullock's blood and lime, I shall be glad if any of your readers can suggest any difference between the two which would be likely to alter the cement.—C. E.

MEETINGS FOR THE WEEK.

MONDAY, June 3rd.—Royal Institution, 3. General Monthly Meeting. London Institution, 4. Prof. Bentley, F.L.S., "On Elementary Botany."
TUESDAY, 4th.—Royal Institution, 3. E. D. Tylor, F.R.S., "On the Development of Belief and Custom amongst the Lower Races of Mankind."
Zoological, 9.
WEDNESDAY, 5th.—Microscopical, 8. Geological, 8.
THURSDAY, 6th.—Royal Society Club, 6. Royal Institution, 3. Prof. Tyndall, LL.D., F.R.S., "On Heat and Light."
FRIDAY, 7th.—Royal Institution, 9. Dr. Odling, F.R.S., "On the History of Ozone."
Geologists' Association, 8.
SATURDAY, 8th.—Royal Institution, 3. Prof. Roscoe, F.R.S., "On the Chemical Action of Light."

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of Six dollars or £1 2s. 4d. per annum payable in advance.

NEW EDITION OF MILLER'S CHEMICAL PHYSICS.

Now ready, in 8vo., with 274 Woodcuts, price 15s. cloth,

Elements of Chemistry, Theoretical and Practical: Part I., CHEMICAL PHYSICS. By WILLIAM ALLEN MILLER, M.D., D.C.L., F.R.S., &c., late Professor of Chemistry in King's College, London. The Fifth Edition, revised, with Additions, by HERBERT MACLEOD, F.C.S., Professor of Experimental Science, Indian Civil Engineering College, Cooper's Hill.

London: Longmans, Green, and Co., Paternoster Row.

In One Volume, 8vo., with Woodcuts, price 7s. 6d.,

A Manual of Chemical Physiology, including its Points of Contact with Pathology. By J. L. W. THUDICUM, M.D.

London: Longmans, Green, and Co., Paternoster Row.

Nearly Ready, Fifth Edition,

A Plea for Reflectors. Being a description of the new Astronomical Telescopes with Silvered Glass Specula, and instructions for adjusting and using them, and Silvering Glass Specula; with full page Chromo-Lithograph of Jupiter, and numerous Illustrations, additional matter, and a simple method of adjusting an Equatorial. By JOHN BROWNING, F.R.A.S., M.R.I., &c., &c. Price 1s.

Also, Nearly Ready,

An Illustrated Descriptive Catalogue of SPECTROSCOPES and SPECTRUM APPARATUS, with Chromo-Spectrographic Chart of Spectra, and Appendices, How to use a Spectroscope, a Micro-Spectroscope, a Tele-Spectroscope, and Screen Spectrum Apparatus. Price 1s. 6d., post free. JOHN BROWNING, Optical and Physical Instrument Maker to the Royal Observatory, &c., &c., 63, Strand, W.C., and 111, Minories, E. Prize Medal, 1862. Established 100 years.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

Now ready, 4th thousand, price 1s.

Psychic Force and Modern Spiritualism: a Reply to the "Quarterly Review" and other critics. By WILLIAM CROOKES, F.R.S., &c. To which is added Correspondence upon Dr. Carpenter's asserted refutation of the author's experimental proof of the existence of a hitherto-undetected force.

"The correspondence impresses us—less from anything it says, than from what it avoids saying—with the notion that the Fellows of the Royal Society are so susceptible to a possible charge of engaging in investigations that may have ridicule attached to them, that they do not give Mr. Crookes fair play. . . . Mr. Crookes certainly comes out of this correspondence better than his correspondents."—*Spectator*.

London: Longmans, Green, and Co., Paternoster Row.

Chemical Technology, or Chemistry in its

Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND CO., 20, King William Street, Strand.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has had laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871—1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

PATENTS.

MR. VAUGHAN, F.C.S., Memb. Soc. Arts, British, Foreign, and Colonial PATENT AGENT, 54, Chancery Lane, W.C., gives special attention to Inventions connected with Chemistry, Metallurgy, and Mining.

A "Guide to Inventors" Free by Post.

THE CHEMICAL NEWS.

VOL. XXV. No. 654.

DOUBLE SULPHIDE OF GOLD AND SILVER.*

By M. M. PATTISON MUIR, F.C.S.

ABOUT eight months ago, at the Thames Goldfield, New Zealand, my brother, Mr. John M. Muir, in conjunction with Mr. William Carrick, made some experiments upon the action of sulphur on a molten mixture of gold and silver, with the view of applying the reaction to the separation of these metals on the large scale. These experiments resulted, however, somewhat otherwise from what they had expected; instead of a complete separation of gold and silver being effected by means of the formation of a sulphide of silver, they found what seemed a new compound produced. A sample of this substance they sent to me, an analysis of which I hope will not prove wholly uninteresting.

Before proceeding to the actual analysis of the substance, I shall briefly state the general method employed by my brother and Mr. Carrick when studying the action of sulphur on gold and silver. The crude gold containing silver was placed in a large pot upon the furnace, where it stood until the contents were molten. Into an iron mercury-bottle turned upside down, by means of a screw-tap, was poured a quantity of sulphur; fitted to the other, that is, the downward end of the bottle, was a plumbago pipe. The sulphur in the bottle, by means of a furnace-fire, was now rendered liquid, and the bottle swung over the pot containing the molten gold and silver. The lower end of the plumbago pipe having been inserted beneath the surface of the molten mixture, the sulphur was allowed to flow down the pipe, and bubble through the contents of the pot. Before doing this, however, a thin film of borax was spread over the molten gold and silver. Quantities of Thames gold, varying from 20 ozs. to 160 ozs., were then treated, the operation being continued from ten minutes to an hour.

At the end of this treatment with sulphur, the pot was taken off the fire, and the gold allowed to solidify, the liquid borax and what they supposed to be sulphide of silver being then poured off. The borax was easily broken off after cooling, and the sulphide obtained as a cake. It was invariably, in all the experiments which my brother and Mr. Carrick conducted, found that the assay of the gold rose from 654 to 812, but there remained stationary, showing that by no means all the silver was extracted. The substance which they supposed to be a double sulphide of gold and silver,—and this supposition, has, I think, been confirmed by analysis,—is a dark grey, hard solid, very much resembling many specimens of native Sb sulphide. It has a crystalline structure, can be cut by a knife, but is very brittle, and has a specific gravity of 8.159. By heating in a current of air, it remains undecomposed. But, by fusion with Na_2CO_3 , a sulphide of Na is formed, and a second alloy of gold and silver remain. After protracted boiling in strong HNO_3 , almost all the silver is dissolved, leaving nearly pure metallic gold. I found that by gentle heating with strong H_2SO_4 for a long time, and subsequent treatment with hot water, it is possible to obtain all the silver in solution, the gold being left behind as a finely divided powder.

1.1915 grms. thus treated gave 0.4252 grms. of gold = 35.569 per cent. The filtrate, precipitated with HCl , gave 0.7799 grms. AgCl = 0.5870 Ag = 49.27 per cent. Another portion, weighing 0.5475 grm., heated gently

with strong HCl and HClO_3 , gave in the solution a precipitate of BaSO_4 = 0.6414 = S , 0.0885 = 16.17 per cent.

From the results of my analysis, I have deduced the formula for the substance of $2(\text{Au}_2\text{S}_3)_5(\text{Ag}_2\text{S})$.

The percentage amounts required by this formula, together with those actually obtained, are given below:—

	Calculated.	Found.
Sulphur	15.87	16.17
Gold	35.47	35.69
Silver	48.66	49.27
	100.00	101.13

ANALYSIS OF SOME CRYSTALS DEPOSITED

UPON THE

ZINC OF A LECLANCHE BATTERY.

By GEORGE E. DAVIS.

In the month of July, 1871, I put up an electric bell at my residence, which was worked by two cells of a Leclanché battery. These cells were of the Bunsen form,—zinc cylinders, with a carbon block in a porous pot. The carbon block was packed into the porous pot, with a mixture of pounded gas-carbon and manganese dioxide, to within half an inch of the top, and the pot was then filled to the top with melted resin, to which bees'-wax had been added to prevent cracking. All the dust was carefully sifted from the carbon-manganese mixture, that used resembling a very coarse gunpowder, and the solution used was a saturated one of ammonium chloride. At the end of February, 1872, the battery began to exhibit signs of exhaustion, and ultimately, early in March, refused to act altogether, except when the circuit was kept closed for a long period of seconds. I may as well add that evaporation was compensated for by the periodical addition of distilled water, nothing else being added to the battery.

On taking the battery to pieces, for the purpose of cleaning it, the porous pot was found to be encrusted with a white insoluble powder: the zinc cylinder was also encrusted, but to a less extent, and from it grew seven or eight opaque white crystals, of the second system,—perfect octahedrons having square bases: they were washed with distilled water, and dried over sulphuric acid.

A qualitative analysis showed me zinc oxide, chlorine, and ammonia, so the quantitative was an easy operation. Only the zinc oxide and the chlorine were determined, as they were deemed sufficient to elucidate the composition of the crystals.

α. 0.91 grm. of the crystals gave 0.48 grm. of ZnO , or 52.74 per cent.

β. 0.7 grm. of the crystals gave 0.37 grm. of ZnO , or 52.85 per cent.

γ. 0.58 grm. gave 0.55 grm. of AgCl , or 23.44 per cent of chlorine.

These numbers obtained agree closely with the formula $\text{ZnH}_2\text{O}_2\text{NH}_4\text{Cl}$, thus:—

	Calculated.	Found.
ZnO	81.0	52.74
H_2O	18.0	52.85
NH_4	18.0	—
Cl	35.5	23.44
	152.5	100.00

Cold water dissolved but little of the ammonium chloride out of the powdered crystals, but when boiled with a large quantity of water the salt is decomposed, ammonium chloride dissolving, and leaving behind the zinc hydrate.

ON THE LAST NEW METAL, INDIUM.*

By WILLIAM ODLING, M.B., F.R.S.,
Fullerian Professor of Chemistry, R.I.

(Concluded from page 254).

THE chief point of chemical interest with regard to any newly-discovered element, and consequently with regard to indium, is the establishment of its atomic weight, which, in the case of a metallic element, is based primarily upon the determination of the ratio in which it combines with oxygen and chlorine. Now the quantity of indium which unites with 8 parts by weight of oxygen and with 35.5 parts by weight of chlorine, has been found by Winkler to be 37.9, and by Bunsen to be 37.8 parts. But this determination of combining ratio falls far short of the definite establishment of the atomic weight of the metal. For example, the quantities of silver, mercury, bismuth, tin, and tantalum, which exist in the best-known chlorides of these metals combined with 35.5 parts of chlorine, are 108, 100, 70, 29, and 37 parts respectively. Nevertheless, the atomic weights of these metals are taken to be not 108, 100, 70, 29, and 37, but 108, 200, 210, 118, and 184 respectively, the chlorides of the several metals being expressed by the formulæ AgCl_2 , HgCl_2 , BiCl_3 , SnCl_4 , and TaCl_5 , respectively. Accordingly, in order to deduce the atomic weight of indium from the ascertained composition of its chloride, we require first to know whether its chloride is a mono-, di-, tri-, tetra-, or penta-chloride. Now, in the case of a metal forming only one definite chloride, the constitution of the chloride as a mono- or poly-chloride, may frequently be determined by a consideration of the analogies presented by the metal and its compounds to some other metal and its compounds, of which the atomic weight and molecular formulæ respectively are well established. But it is obvious that analogy can afford but little help in the case of a newly-discovered element, of which the analogies have still to be determined.

Failing analogy, a more sure guide to the establishment of the molecular formula of a metallic chloride is afforded in some instances by a determination of its vapour density, —tantamount to a determination of the quantity of chlorine by weight, contained in a given volume of the gas or vapour of the chloride experimented on. Thus, having estimated the quantity of chlorine contained in a given volume of heated muriatic acid gas, the quantities of chlorine contained in the same volume of the vapourised chlorides of mercury, bismuth, tin, and tantalum, under the same circumstances of pressure and temperature, are found to be 2, 3, 4, and 5 times as great, whence the formulæ HCl , HgCl_2 , BiCl_3 , SnCl_4 , and TaCl_5 , respectively. Now indium chloride being volatile at a red heat, there is no reason, save that resulting from the rarity and value of the body, why the density of its vapour should not be ascertained. As a matter of fact, however, no estimation of the vapour density of indium chloride has yet been made, and any evidence that might be deducible from it is consequently not forthcoming.

Lastly, a most important guide to the establishment of the atomic weight of a metal is the determination of its specific heat. In cooling through the same fall of temperature, different bodies, as is well known, give out exceedingly different quantities of heat. In the case of a pound of bismuth and a pound of brass, for instance, both raised to the temperature of boiling water, and then immersed in an excess of ice, the quantity of ice melted by the pound of brass in cooling down to the freezing-point, will be found to be more than three times as great as the quantity of ice melted by the pound of bismuth. Now the determination of the specific heats of most of the metals, compared with the specific heat of an equal weight of water as unity, has been made with extreme

care and exactitude by Regnault; and on looking at the following list of specific heats, mostly of his determination, it is evident, almost at a glance, that the specific heats of the metallic elements are inversely as their respective atomic weights. Thus, taking the first and last elements on the list for example, it is observable that the specific heat of lithium, or 0.94, is weight for weight thirty times greater than the specific heat of bismuth, 0.03; but then the atomic weight of bismuth is thirty times greater than that of lithium. And throughout, the product of the specific heat into the atomic weight of one metal, divided by the product of the specific heat into the atomic weight of another metal, is approximately equal to 1, as shown in the fourth column of the following table, in which the product of the specific heat into the atomic weight of silver is taken as the standard dividend. Now, only last year, concordant estimations of the specific heat of indium were made by Bunsen and a Russian chemist, Mendelejeff; the mean of Bunsen's two estimations being 0.0569, which, it will be observed, is very close to Regnault's estimations of the specific heats of silver, cadmium, and tin. Accordingly, the atomic weight of indium must approximate to the atomic weights of silver, cadmium, and tin; or, in other words, it cannot be 37.8×1 , or 37.8×2 , but must be $37.8 \times 3 = 113.5$; and the quantity of chlorine combined with this weight of indium being three times 35.5 parts, indium chloride will necessarily appear as a trichloride, and be expressed by the formula InCl_3 . The determination of specific heats being a matter of direct experiment, with scarcely any ratiocination whatever, it seems impossible for anyone to observe the relationship subsisting between the accepted atomic weights of the metals, deduced from experiment by a highly complex train of reasoning, and their directly ascertained specific heats, without recognising that in the case of the metals, at any rate, the atomic weights of the chemist are something more than vain imaginings, but that they are beyond question the terse expression of a fundamental truth in nature.

The most important chemical characters of indium being thus established, there remains for consideration only the question of its affinities to certain of the previously-known elements. And seeing that the atomic weights of the elements range from 1, the atomic weight of hydrogen, up to 240, the atomic weight of uranium, there opens out the further question, whether the more obvious chemical properties of the different elements are seriated in any way with their atomic weights; or to put this last question in another form, whether the varied chemical properties of the elements are distributed among them haphazard, or according to some definite system of which the relationship subsisting between their several atomic weights may possibly serve as a key. Now the atomic weights, as distinguished from the combining proportions, of yttrium, erbium, cerium, lanthanum, and didymium, must be regarded for the present as quite unknown. Out of the fifty-eight elements, however, of which the atomic weights have been more or less well-determined, forty-six have their several atomic weights ranging from 1 to 137, in an almost unbroken succession. Ten of the other twelve have atomic weights ranging from 184, that of tantalum, to 210, that of bismuth; while the remaining two, namely, thorium and uranium, have the closely-approximating atomic weights 238 and 240 respectively. In the above Table, the symbols of the forty-six elements having atomic weights ranging from 1 to 137, are set down in the order of the atomic weights of the elements symbolised,—save only in the case of tellurium, of which the symbol is placed immediately above, instead of below, that of iodine, and of which the atomic weight may not improbably have been somewhat over-estimated. And violating the order of numerical seriation in this small particular only, it is remarkable with what facility the symbols of the forty-six elements may be arranged in parallel lines and columns, corresponding to a natural classification of the elements themselves into analogous groups and series. Indeed, a study of the entire number of elements at present known would seem to indicate that they are one and all associated with each other by a certain community of relationship; of which the well-known gradation and parallelism in properties and atomic weights, of the members of the alkali and earth-alkali, and of the halogen and oxygen families of elements, afford only the most prominent examples.

Taking the second line of the Table as an illustration, it is observable that the seven metals symbolised thereon are distinguished from all the others by their common property of forming one chloride only, and that a di-chloride; further, that the metals figuring in the uneven-numbered columns of this line, namely, magnesium 24, zinc 65, and cadmium 112, are permanent in the air, are volatilisable in the direct and basylous in the inverse order of their atomic weights, and are otherwise specially associated with one another; while the similarly associated metals of the alternate or even-numbered columns, namely, calcium 40, strontium 87.5, and barium 137, are quickly oxidisable in the air, are practically non-volatile, and are basylous in the direct instead of the

inverse order of their atomic weights; and similarly, on the other lines of the Table, the elements symbolised are divisible into sub-groups, according to their odd and even positions respectively.

Such being the relationship of the elements placed on the same line, the relationship of those in the same column is of a different kind. Taking the third and seventh columns by way of illustration, it is observable that the consecutive elements in each column have closely consecutive atomic numbers; that the element on the first line forms a mono-chloride; that on the second line, a di-chloride; that on the third line, a tri-chloride; and that on the fourth line, a tetra-chloride; while those on the fifth, sixth, and seventh lines form oxides or oxychlorides, corresponding to a penta-, hexa-, and hepta-chloride respectively.

By reason of its atomic weight, 113.5, indium is observed to figure on the third line and seventh column of the above Table; but its position among the elements is better recognisable by a glance at the Table below, containing a portion only of the preceding one, supplemented by an additional column of elements of higher atomic weight than any of those included previously.

In respect of its atomic weight, then, triad indium occupies a position exactly intermediate between the positions of diad cadmium and tetrad tin, to both of which metals it presents a most marked resemblance in properties. They all three have the same extreme degree of fusibility, and much the same oxidisability and reducibility. Their sulphides are alike characterised by a yellow colour, that of cadmium, CdS, being neutral; that of tin, SnS₂, being acidulous; and that of indium, In₂S₃, being strictly intermediate.

	3.	7.	10.	Type.
I. ..	Na 23	Ag 108	—	RCl
II. ..	Mg 24	Cd 112	Hg 200	RCl ₂
III. ..	Al 27.5	In 113.5	Tl 203	RCl ₃
IV. ..	Si 28	Sn 118	Pb 207	RCl ₄
V. ..	P 31	Sb 122	Bi 210	RCl ₅
VI. ..	S 32	Te 129	—	RCl ₆

Viewed in another aspect, triad indium occupies a position intermediate between the positions of its remote triad congeners, aluminium and thallium. The mean atomic weight of the three metals being 114.3, the atomic weight of indium is 113.5. The mean specific gravity of the three metals being 7.3, the specific gravity of indium is 7.4. And in respect of purely chemical habitudes, hydrated alumina and hydrated india might easily be mistaken for one another. It is interesting, moreover, to remark that the last-discovered two metals indium and thallium—discovered, it will be remembered, by the same process, that of spectrum analysis—should bear to one another much the same sort of relation that is borne to one another by the jovian and saturnine metals of the alchemical or even pre-alchemical era. Just, for example, as the unstable and least-known chloride of lead, PbCl₄, corresponds to the stable chloride of tin, SnCl₄, so does the unstable and least-known chloride of thallium, TlCl₃, correspond to the stable, and as yet only known, chloride of indium, InCl₃, as suggested, indeed, by the lecturer some six or seven years ago.

The study of such relationships necessarily suggests many inquiries. Arranging the entire fifty-eight elements of which the atomic weights are known, in a table similar to the preceding one for the forty-six elements having atomic weights not exceeding 137, some twenty or five-and-twenty new elements would be required to fill up the gaps in the different series; but why should not new elements be discovered having atomic weights as much above that of uranium, 240, as its atomic weight is above that of barium, 137?

Again, does it seem probable that bodies capable of being arranged in such a well-marked numerical series, are really elementary and mutually independent; or is it more likely that the gradation of properties and atomic

* This Table is based on one published by the author in 1864-5. Similar tables have been constructed by Newlands, Meyer, Mendeleeff, and others. The positions marked Xa, Xb, and Xc, are assigned by Mendeleeff to yttrium, didymium, and cerium, respectively. The recognition of the atomic weight of uranium as 240, is also due to Mendeleeff.

numbers manifested by these bodies, depends on their possession of different increments of common material?

May it not be that the numerical ratio between the atomic numbers of proximate elements, $\frac{x}{y}$ = approxima-

tively $\frac{y}{x}$, is really absolute; and that it will hereafter be proved to be so by a better determination of atomic weights. Seeing that a short time back, caesium with the atomic weight 133, and rubidium with the atomic weight 85, both occurred as unrecognised impurities in potassium with its atomic weight 39, who shall answer for the absolute accuracy of even the best established of our present atomic weights?

Again, the mean difference in atomic weight between consecutive analogous elements is, in the case of the nine following pairs of elements, lithium and sodium, glucinum and magnesium, boron and aluminum, carbon and silicon, nitrogen and phosphorus, oxygen and sulphur, fluorine and chlorine, sodium and potassium, magnesium and calcium, 16.1; the lowest difference being 15, and the highest 17. The mean difference in the case of the four following similar pairs of proximate elements, phosphorus and vanadium, sulphur and chromium, chlorine and manganese, arsenic and niobium, is 19.25; the lowest difference being 19, and the highest 20.5. Lastly, the mean difference in the case of the seven following similar pairs of proximate elements, calcium and zinc, vanadium and arsenic, manganese and bromine, rubidium and silver, strontium and cadmium, silver and caesium, tantalum and bismuth, is 24.6; the lowest and highest differences, even in the case of these elements of such high atomic weight, being 23 and 26 respectively. Are these differences in atomic weight only approximately, or are they indeed absolutely, 16, 20, and 24 respectively; and if so, why should the numerical difference between proximate associated elements be 16 in one set of cases, 20 in another set, and 24 in a third?

ON THE
PART WHICH FERRIC AND ALUMINIC OXIDES
PLAY IN THE MANUFACTURE OF
SUPERPHOSPHATE;

AND ON THE
COMPARATIVE VALUE OF MINERAL
PHOSPHATES.*

By T. L. PATTERSON, F.C.S.
(Concluded from p. 257.)

The Comparative Value of Mineral Phosphates.

CONTINUING to speak of these from a decomposition point of view, and assuming that the tricalcic phosphate is the only valuable ingredient they contain, it will be necessary to consider how far their value is modified by the presence of ferric and aluminic oxide, which, I have just shown, reduce or render insoluble a portion of the phosphoric acid.

It is well known that superphosphate of lime, when applied to the soil, soon has its phosphoric acid precipitated as insoluble tricalcic phosphate, by means of the earthy carbonates contained therein. And it is admitted by all chemists that such precipitated tricalcic phosphate possesses with soluble phosphate of lime, the same value as a fertiliser. It is also admitted by chemists that the great value of soluble or precipitated tricalcic phosphate, compared with mineral phosphates, depends wholly on the much greater solubility of the former. By determining, then, the solubility of ferric and aluminic phosphates, we will be in a position to form more correct

notions as to their mamurial value. I therefore made two other experiments to clear up this point.

Expt. 10.—Carbonic acid gas was continuously passed through distilled water holding pure precipitated tricalcic phosphate (thoroughly washed and dried in the water-bath) in suspension for five hours, when the undissolved portion was removed by filtration. On heating a portion of the filtrate to boiling with nitric acid and ammonia molybdate, a considerable yellow precipitate was obtained. To another portion of the filtrate was added one drop of a solution of ferric alum, when a slight precipitate was immediately produced. After standing some time, it collected at the bottom of the vessel. The phosphate of lime solution was now added in excess, and the ferric phosphate filtered off. The filtrate gave no blue colour with ferrocyanide, and only a faint reddish tinge with sulphocyanide of potassium, when acidified with HCl. To a third portion of the filtrate ferric alum was added in excess, when the precipitate at first formed re-dissolved. To a fourth portion of the filtrate a drop of aluminic alum was added. An opalescence was immediately produced, and after standing some time, a precipitate of aluminic phosphate separated. When the alum solution was added in excess, the precipitate was re-dissolved. On separating the aluminic phosphate precipitate,—after a carefully conducted precipitation to insure the merest trace of alum in excess,—a drop of the ferric alum produced in the filtrate a second precipitate of ferric phosphate; thus showing aluminic phosphate to be the more soluble of the two.

Expt. 11.—Very finely ground and washed coprolite, suspended in distilled water, was subjected to a continuous stream of CO₂, as was the pure tricalcic phosphate in Experiment 10. The undissolved portion was then filtered off, and the filtrate, when tested with molybdic acid solution, only gave a slight trace of a yellow precipitate. On evaporating the filtrate to one-fourth, however, good evidence of the presence of phosphoric acid was obtained. Aluminic alum produced in the filtrate a barely perceptible opalescence, which, after standing some time, collected as a precipitate at the bottom of the vessel. This precipitate was removed by filtration, and tested with molybdic acid, after solution in dilute nitric acid. A considerable yellow precipitate proved the presence of phosphoric acid. The filtrate evaporated to one-fourth only gave a trace of a yellow precipitate with molybdenum solution. To another portion of the coprolite solution I added a drop of ferric alum; an opalescence was immediately produced. With a slight excess of the precipitant, the precipitate has a yellow colour, caused by the calcic carbonate in solution throwing down hydrated ferric oxide; and when the precipitant is in great excess, no precipitate at all is formed, or that at first formed is re-dissolved. (This is also the case with an excess of aluminic alum). On removing the yellow precipitate thus formed, and dissolving it in dilute nitric acid, abundant evidence of the presence of phosphoric acid was obtained, on heating the solution with molybdic acid to boiling. The filtrate, when evaporated to one-fourth, gave the merest trace of a yellow precipitate when tested with molybdic acid.

The results of these experiments are similar to some made by Warrington* with another object in view. I thought this precipitation method of experimenting preferable to dissolving separate portions of each in carbonic acid, and determining the amount dissolved, as it produces a minute quantity of these phosphates in the very best possible condition for solution; and, as it has turned out, shows at a glance how insoluble they are compared with ground coprolite and pure tricalcic phosphate. If we arrange them in the order of their solubilities, coprolite will come first, aluminic phosphate next, and ferric phosphate last. I forget the actual solubility of coprolite, and cannot remember where I have seen it stated. Bischof†

* Read before the Chemical Section of the Glasgow Philosophical Society, April 29th, 1872.

† CHEMICAL NEWS, vol. xvi., p. 253, and vol. xxi., p. 227.

† "Chemical and Physical Geology," vol. ii., p. 34.

gives the solubility of wavellite as one part in 6,828,000 parts of carbonic water; but it is likely the precipitated aluminic phosphate here referred to is much more soluble than that. And ferric phosphate must be very slightly soluble indeed, when we consider the extreme delicacy of the sulphocyanide test for iron, and the molybdate of ammonia test for phosphoric acid, and that only minute traces of these bodies were found in the filtrate from the ferric phosphate precipitate.

Now, most agricultural authorities are agreed that ground coprolite in a superphosphate is worthless. Voelcker says, "Insoluble phosphates in the shape of coprolite powder are not worth anything in an artificial manure, for they are too insoluble to be taken up by the turnip-crop." Of what value, then, is ferric phosphate and aluminic phosphate in a manure? These experiments show, I think, that they have none whatever. But, it may be said, the manufacturer can hardly be expected to lose the phosphoric acid which has thus become unavailable. Neither, would I say, has he any right to charge it to the farmer as precipitated phosphate of lime; he should rather see that he does not pay more than the raw material which contains these objectionable oxides is worth. He will then be able to sell his superphosphate as it ought to be sold,—viz., as valuable only for that portion of phosphoric soluble in water.

At first sight it might appear that Warington's experiments on the absorptive power of soils † contradict all that I have said regarding the worthlessness of the phosphates of ferric and aluminic oxides. He endeavours to prove that hydrated ferric and aluminic oxides in the soil ultimately convert all phosphoric acid added as manure into basic phosphates of these oxides. But a careful study of his results shows, I think, that the conversion of precipitated tricalcic phosphate into ferric and aluminic phosphates is very gradual, and points to the probability of its being a long time before all the phosphoric acid could be thus transformed. My own experiments are in the same direction. In Experiment g I have shown how very slowly hydrated ferric oxide removes phosphoric acid from an acid solution. And again, in superphosphate, how slowly ferric and aluminic hydrates precipitate a portion of the phosphoric acid. The fact still remains, too, that root-crops are greatly increased in quantity by the addition of superphosphate of lime to the soil, from the precipitated phosphate of lime thus produced being comparatively more soluble, and easily assimilated by plants. These considerations lead me to think that the rootlets of plants abstract tricalcic phosphate from its CO₂ solution almost as quickly as it is dissolved, and before the ferric and aluminic oxides have had time to absorb any appreciable quantity of it. It is only after the roots have taken what they require that the absorptive action of these oxides will come into full play, and go on precipitating the remaining portion, to give it up very slowly again at some future period to a crop requiring little phosphoric acid; for, as the rootlets feed almost wholly on salts in solution, it is difficult to conceive how a quick-growing plant which requires much phosphoric acid could assimilate a sufficient quantity from such insoluble materials, and ones, too, the affinities of whose components are so very great. And as, moreover, mineral phosphates are only treated with acid to make them more soluble, for the very purpose of rendering the soil more productive and increasing our crops, we are driven to the inevitable conclusion that any phosphate in a manure less soluble than precipitated tricalcic phosphate,—and certainly any less soluble than ground coprolite,—must be worthless as a fertiliser.

Such being the case, I submit that the present method of valuing a mineral from the percentage of phosphate of lime alone which it contains, is a very erroneous one, and ought to undergo some modification whereby these oxides are taken into account in the valuation. To do

this, it will be necessary to calculate—1st, what we may call the "net realisable per cent" of phosphate of lime obtainable from any sample; and 2nd, the weight per cent of sulphuric acid required to reduce it to this condition. With these data, and the known composition and value of some sample taken as a standard, it will be possible to ascertain, very closely indeed, the comparative value of another mineral phosphate.

First, then, in order to find the net realisable percentage of phosphate of lime, we must know, by analysis, the actual percentage of phosphate of lime, ferric oxide, aluminic oxide, and ferrous oxide, which the mineral contains: knowing this, it is simply necessary to calculate for each of these oxides equivalent quantities of phosphate of lime, and deducting the sum of the three from the actual percentage of that earth, the remainder will be the net realisable percentage of phosphate of lime in the sample. If the ferric oxide be multiplied by the factor—

$$1.9375, \left(\frac{155}{80} = 1.9375 \right),$$

the aluminic oxide by—

$$3.0156, \left(\frac{155.0}{51.4} = 3.0156 \right),$$

and the ferrous oxide by—

$$2.1528, \left(\frac{155}{72} = 2.1528 \right),$$

the amount of tricalcic phosphate equivalent to these oxides is at once found.

And, second, to calculate the weight of sulphuric acid required to reduce the mineral to the condition of net phosphate of lime, we must know the percentage of calcic carbonate, besides that of the ferric and aluminic oxides. If any peroxide of iron and alumina exist as phosphates of these oxides,—and this is sometimes the case,—such oxides are not taken into account in this calculation. The acid I propose to use has a gravity of 1.734 = 147° T., and contains 80 per cent of H₂SO₄. This is of commercial strength, so that a value can always be assigned to it.

1 molecule of CaCO₃ requires 1 of H₂SO₄.

1	"	Fe ₂ O ₃	"	3	"
1	"	Al ₂ O ₃	"	3	"
2	"	FeO	"	3	"

Calculating a factor for each of these, whereby the weight of acid of the above strength may be found for all of them, we have the percentage of—

CaCO ₃ × 1.225	= acid at 147° T.
Fe ₂ O ₃ × 2.297	" "
Al ₂ O ₃ × 3.575	" "
FeO × 2.552	" "

and the sum of the products is the acid required.

It is thus assumed, that were that quantity of acid added to a mineral phosphate, and the mixture allowed to stand some time, as is the case in practice, the product would consist—so far as the bases and acids are concerned—of tricalcic phosphate, ferric phosphate, aluminic phosphate, and calcic sulphate, and the amount of the first in the mixture would be what I have called the net realisable phosphate of lime.

Before concluding, I will just go through the calculation necessary to find the value of one of these phosphates. In No. 2 sample we have—

Fe ₂ O ₃ = 2.03 per cent	× 1.9375 = 3.93	Ca ₃ (PO ₄) ₂
Al ₂ O ₃ = 1.75 "	× 3.0156 = 5.28	"
FeO = 0.34 "	× 2.1528 = 0.73	"

Total 9.94

And 55.02 - 9.94 = 45.08 per cent of net phosphate of lime. The acid is found as follows:—

CaCO ₃ = 24.47 per cent	× 1.225 = 29.97	acid.
Fe ₂ O ₃ = 2.03 "	× 2.297 = 4.66	"
Al ₂ O ₃ = 1.75 "	× 3.575 = 6.26	"
FeO = 0.34 "	× 2.552 = 0.87	"

Total 41.76 "

* Article on Manure, in Ure's "Dictionary," vol. iii., p. 50.
† CHEMICAL NEWS, vol. xxi., p. 207.

100 parts of this phosphate are thus shown to yield 45.08 parts of net phosphate of lime, with the consumption of 41.76 parts of sulphuric acid of 1.734 sp. gr. When Nos. 1 and 3 are calculated in the same way, we see at a glance that No. 3 is superior to No. 2, although it contains less phosphate of lime; and again, because No. 1 contains so much oxide of iron and alumina, how inferior it is to either of them.

	Net Phosphate of Lime.	Sulphuric Acid, 1.734 sp. gr.
No. 1.	24.82 with a consumption of	42.69
No. 2.	45.08 " "	41.76
No. 3.	46.52 " "	24.70

Taking, now, the price of vitriol at 80s. per ton, and that of the mineral phosphate No. 3 as a standard at 52s. per ton, which prices are about their present market value, we can easily calculate the comparative value of the other two: 52s. for 46.52 per cent = 1.118s. for 1 per cent. In No. 2 we have $45.08 \times 1.118s. = 50.48s.$ per ton. But as No. 2 consumes more acid than No. 3, the value of the excess must be deducted from the price so found, to place the two on equality: $41.76 - 24.70 = 17.06$ acid, at $147^{\circ} T.$, at 80s. per ton; $= \frac{17.06}{100} \times 80s. = 13.65s.$, and $50.48 - 13.65s. = 36.75s.$, or 36s. 9d., as the true value of No. 2 compared with No. 3 at 52s. per ton. When No. 1 is calculated in the same way, it is found to have a value of only 13.35s., or 13s. 4d. per ton.

NOTES OF WORK BY STUDENTS' OF PRACTICAL CHEMISTRY IN THE LABORATORY OF THE UNIVERSITY OF VIRGINIA.

Communicated by J. W. MALLET, Ph.D., M.D.,
Professor of Analytical and Applied Chemistry, University of Virginia.
(Concluded from p. 259).

(5). Detection of Lead as an Impurity in "Iron reduced by Hydrogen." By Mr. J. W. C. DAVIS.

A SPECIMEN of "iron reduced by hydrogen," obtained from the eminent firm of E. Rousseau, of Paris, was found to contain lead to the extent of 1.287 per cent of the metal. How this impurity was introduced is not easy to imagine. Its presence is worthy of notice, in view of the pretty large doses of iron by hydrogen sometimes used in medical practice.

(6). Analysis of Genthite (Nickel-Gymnrite) from North Carolina. By Mr. F. P. DUNNINGTON.

Among a number of minerals kindly sent by Mr. J. A. Reagan, of Tennessee, a laboratory student of last year, there were several specimens of genthite from Webster, Jackson Co., N.C., a locality at which the species is reported,* but without any chemical analysis that I have seen. It occurs as an incrustation, usually not more than a millimetre in thickness, of delicate apple-green colour and resinous lustre, translucent, and of specific gravity = 2.48 at $19^{\circ} C.$, completely decomposable by hydrochloric acid. Some portions were greenish-white and opaque: these were rejected as having probably suffered alteration. Very carefully chosen fragments of the pure mineral, having been pulverised and exposed for some time to the atmosphere of a bell-glass over oil of vitriol, gave on analysis:—

Silica	49.89
Magnesia	22.35
Nickel monoxide	16.60
Iron monoxide	0.06
Water	12.36

101.26

(Of the water 6.00 was lost at $100^{\circ} C.$)

* Dana's "Mineralogy," 5th ed., pp. 471 and 782.

The analysis is not a very satisfactory one, the sum of the constituents found exceeding 100 per cent of the mineral by rather more than a reasonable allowance of error. It was not repeated, from want of sufficient material from which to select fragments that could be relied upon as pure.

So far as the above numbers go, however, they do not correspond to the formula assigned to genthite, namely, $(\frac{1}{2}(MgO, NiO) + \frac{1}{2}H_2O)_2, SiO_2 + \frac{1}{2}H_2O$, i. e., deweyllite or gymnrite with MgO partly replaced by NiO, but (with the whole of the water) more nearly represent a nickel-aphrodite, $(MgO, NiO), SiO_2 + \frac{1}{2}H_2O$. The previously recorded analyses of genthite from other localities do not agree well with each other, and leave room for useful revision.

(7). Analysis of a Mineral from Webster, Jackson Co., North Carolina. By Mr. F. P. DUNNINGTON.

In the same lot of minerals in which the genthite was received there was a specimen of a material much resembling in appearance pimelite from Silesia, but which proved to contain no nickel. It was massive, with indistinct traces of fibrous structure, moderately brittle, with earthy fracture, of slightly yellowish apple-green colour and greenish-white streak, dull on fractured surface, with faintly greasy lustre where cut or rubbed, feeling greasy to the touch, not adhering to the tongue, hardness = about 1.25, sp. gr. = 2.30 at $18^{\circ} C.$ It was infusible before the blow-pipe, gave off water when heated in a closed tube, and was partly, but not completely, decomposed by strong hydrochloric acid.

Its analysis afforded the following results, the mineral having been previously dried in air, at ordinary temperature and pressure, over sulphuric acid:—

Silica	43.87
Alumina	22.21
Iron monoxide	16.14
Soda	1.05
Water	16.37
	99.64

(Of the water 3.54 was lost at $100^{\circ} C.$)

These figures, if we neglect the small amount of alkali, lead to the formula—

which is not that of any hitherto-described species; but the mineral, though uniform in character, is in all probability a product of alteration, and it seems unwise to add—by another new name for a so-called species—to the already long list of such ill-defined hydrous silicates of earthy character.

(8). Analysis of a Compact Talc from North Carolina. By Mr. J. B. ADGER.

Amongst the minerals above referred to there was a very beautiful "soapstone, from the Nantahela Mountains, 8 miles from the mouth of Nantahela River, Wayne Co. (formerly Cherokee Co.), N.C." It had been sawn into slabs of about $1\frac{1}{2}$ inches thick, was very uniform in character, compact, with indistinct traces of foliated structure, white with a faint greenish shade, lustre pearly, streak white, moderately translucent, greasy to the touch, hardness = about 1.25, sp. gr. = 2.82. It resembled somewhat the finer and light-coloured specimens of Chinese jade or nephrite. Analysis afforded—

Silica	57.72
Magnesia	33.76
Alumina	2.52
Iron monoxide	0.64
Water	6.01

100.65

If the silica, magnesia, and water, alone be considered, the above numbers correspond pretty closely to the formula ($\frac{1}{2}\text{MgO} + \frac{1}{2}\text{H}_2\text{O}$), $\text{SiO}_2 + \frac{1}{2}\text{H}_2\text{O}$.

The mineral is obviously distinct from the foliated talc from Webster, Jackson Co., N.C., analysed by Genth (*Am. J. Sci.*, II., xxxiii., 200, as quoted in Dana's "Mineralogy," 5th ed., p. 453). In the latter 0.23 per cent of nickel oxide was found, and but 0.34 per cent of water.

In the mineral now described there is no nickel.

University of Virginia

NOTE ON A

PORTION OF THE INCRUSTED SURFACE
OF A BLOCK OF JEW'S TIN.

By J. H. COLLINS, F.G.S.,
Secretary of the Royal Cornwall Polytechnic Society.

At a recent meeting of the Royal Institution of Cornwall, a block of "Jew's tin," from Tremethack Moor, in Madron, just purchased for the Institution, was exhibited for the first time to the members. This block was partially covered with a hard and brittle brown coating, in some places as much as $\frac{1}{2}$ inch thick. Mr. W. Jory Henwood, F.R.S., the late President, before the expiration of his term of office, placed a portion of this coating in my hands for analysis.

The brown colour was not evenly distributed, some parts being darker than others; and under the microscope several minute shining particles were visible—probably particles of metallic tin. The specific gravity of the substance was 5.64.

After a few preliminary trials I found I had just 48 grains at my disposal, which I had previously reduced to a fine powder. On drying this powder, at a temperature of 120°C ., it was reduced to 45 grains.

The powder was boiled with distilled water for a time, and yielded a solution from which I obtained 0.5 gr. of tin and 0.3 gr. of chlorine = 0.8 gr. of SnCl_2 . The powder was then digested with aqua regia, when the solution so obtained yielded 0.5 gr. of peroxide of iron, 0.21 of tin, and 0.2 silica. What remained after this treatment was dark brown, very heavy, and much like ordinary "black tin" of good quality, in appearance: when dried it weighed 43.2 grains. This was reduced in a crucible by cyanide of potassium, and yielded 34.12 grains of metallic tin = to 43.5 grs. of SnO_2 .

The quantities thus obtained were calculated to percentages, with the following result:—

Moisture evolved at 120°C .	6.25
Metallic tin	0.43
Chloride of tin	1.66
Peroxide of tin	90.62
Peroxide of iron	1.04
Silica	0.41

100.41

The crust therefore appears to be composed chiefly of peroxide of tin, somewhat resembling that native variety of cassiterite called "wood-tin," but neither so hard nor so heavy. It has no doubt been formed by the slow oxidation of the outer surface of the block of metallic tin. The slowness of the change is, perhaps, indicated by the dense condition of the incrustation.*

* On a similar sample of the same specimen, Mr. James Napier, F.C.S., remarks (20th December, 1871):—

"The incrustation which invests the mass of Jew's-house tin from Tremethack Moor is a pure peroxide of tin with a mere trace of iron; in short, the metal has been re-converted into tin-stone. This is of exceeding interest, as it shows how pure the metal must have been. All analyses of ancient bronze, however, show that the earliest are of the best quality."

APPLICATION OF ELLIOTT'S PROCESS

TO THE

DETERMINATION OF CARBON IN BONE-COAL
GRAPHITE, ANTHRACITE, &c.

By F. A. CAIRNS, A.M.

THE employment, for a long time of Elliott's modification of Uhlgren's process, for the determination of total carbon in cast-iron and steel, as described in the *Journal of the Chemical Society of London*, May, 1869, led me to the application of it, to determining graphite alone, and then to determining carbon in bone-coal and anthracite and bituminous coals, by oxidising directly with chromic and sulphuric acids, in Elliott's apparatus. The advantages of the method are decided in point of time, ease, and neatness, in all the applications of it that have been tried here. In point of accuracy it has not been found inferior to any other. There seems to be an impression with many that nothing equals the old process of combustion in a current of oxygen, but where the oxidation by chromic acid is carefully conducted the results seem to be equally good.

The method proposed by W. D. Herman, in the *Journal of the Chemical Society of London*, June, 1870, for the direct combustion of iron and steel, seems to be superior in point of time and directness.

These advantages are enough to recommend the method, although the results are generally by Hermann's figures a little low, were it not for the expensive and troublesome apparatus required.

The delay in filtering the carbon complained of by Herman is probably owing to the use of funnel tubes of insufficient capacity. The same difficulty has occasionally been encountered here, owing to the cause suggested. The determination of total carbon, or graphite, generally occupies from 5 to 6 hours, after the substance has been prepared. Elliott's method of separating carbon seems peculiarly adapted to steel, the difficulties attending it, by Weyl's and other similar methods, being, as is well known, extremely great.

It is unnecessary, perhaps, to allude to matters of manipulation, as Elliott has given very explicit directions. One point which he does not speak of seems worthy of notice, that is, the final weight of the absorption-tube.

If it should have been standing unused for any considerable length of time previously, it should not be weighed after the operation until it has stood some hours with stoppers on the points, to allow it to become thoroughly cooled. Neglect of this precaution may cause an error of one or two tenths of 1 per cent. It has also been found advantageous to apply an aspirator at the beginning of the operation, to prevent the possibility of loss of carbonic acid, through the-rubber joints, in consequence of great pressure, caused by rapid evolution of gas.

The method, as applied to total carbon in iron and steel, has been thoroughly tested by others.

To test its accuracy in respect to graphite four equal weights of iron were treated by the ordinary method, and in an exactly similar manner to separate the graphite.

The first was oxidised by Elliott's method, giving 1.50 per cent carbon.

The second was burned in oxygen as usual, giving 1.50 per cent carbon.

The third was treated by Elliott's method, giving 1.493 per cent carbon.

The fourth was lost.

The time consumed was about the same, while all the disagreeable concomitants of furnace combustions, preparation of combustion-tube, &c., and accidents, were avoided by following Elliott's method.

Two samples of bone-coal were then heated by combustion in oxygen, and by oxidising directly with chromic acid.

One gramme of the first was burned in oxygen, and the carbonic acid in the ash determined and assured,

giving, after deducting the carbonic acid due to carbonate of lime in the coal, 8.29 per cent carbon.

One-half of a gramme of the same coal was then heated directly with chromic and sulphuric acids, and, after deducting carbonic acid due to carbonates as before, gave 8.20 per cent carbon. One gramme of the second was then burned in oxygen, &c., and gave 10.25 per cent carbon.

One-half of a gramme of the second, treated with chromic acid, &c., gave 10.28 per cent carbon.

The results were so satisfactory that other determinations have been made and compared, and the method adopted in these laboratories for a long time past.

The ordinary method of determining the carbon in bone-coal by loss on igniting the residue, insoluble in chlorhydric acid (previously dried and weighed on a tared filter), is not only imperfect, but involves more time and labour than the oxidation by chromic acid, by which method the determination can be made in less than one hour, saving the delay incident to the cooling of the tube, as suggested before.

The next experiments were made upon anthracite and bituminous coals.

The first taken was a Lehigh anthracite.

The oxygen combustion gave 91.72 per cent, and 91.68 per cent carbon. The direct oxidation by chromic acid and sulphuric acid gave 91.78 per cent carbon. A bituminous coal from Carmelsville, Pa., was then tried. This was a caking coal, and gave a great deal of trouble in the oxygen combustion, with very varying results, viz., 81.29, 82.61, 83.64, and 82.34 per cent. The oxidation with chromic acid gave 83.74 per cent carbon. The operation proceeded with rapidity and ease. In the case of coals, the oxidation should proceed rather slowly, and of course the substance should be very finely pulverised.

Substance.	Weight in grms.	Method.	Time.	Per cent of carbon.
Graphite	1	$\text{H}_2\text{CrO}_4 + \text{H}_2\text{SO}_4$	5 hrs.	1.500
"	2	Combustion in oxygen	5 "	1.500
"	3	$\text{H}_2\text{CrO}_4 + \text{H}_2\text{SO}_4$	5 "	1.493
Bone-coal	1.000	1 { Combustion in oxygen	3 "	8.290
	0.500	1 { $\text{H}_2\text{CrO}_4 + \text{H}_2\text{SO}_4$	1 "	8.200
	1.000	2 { Combustion in oxygen	3 "	10.250
" "	0.500	2 { $\text{H}_2\text{CrO}_4 + \text{H}_2\text{SO}_4$	1 "	10.280
	0.300	{ Combustion in oxygen	4 "	91.720
	0.300	{ $\text{H}_2\text{CrO}_4 + \text{H}_2\text{SO}_4$	2 "	91.680
Anthracite.	0.100	{ $\text{H}_2\text{CrO}_4 + \text{H}_2\text{SO}_4$	2 "	91.780
				81.290
				82.610
Bituminous coal.	0.200	Combustion in oxygen	4 "	83.640
				82.340
	0.100	$\text{H}_2\text{CrO}_4 + \text{H}_2\text{SO}_4$	2 "	83.740

Note.—Since writing the above, my attention has been called to two articles in the *American Journal of Science*, of 1848, by Prof. R. E. Rogers and Prof. Wm. B. Rogers, of the University of Virginia, on 'the determination of carbon in graphite, and the oxidation of the diamond, by means of bichromate of potash and sulphuric acid, with good results, at least as to graphite. By combustion of native graphite in oxygen they obtain 94.16 per cent of carbon, and by the oxidation by means of chromic acid 94.56 per cent. They give no figures in the case of the diamond.

From this it would seem that they are entitled to the suggestion of the use of chromic and sulphuric acids for the determination of carbon.—*American Chemist*.

METHOD OF DETECTING SMALL QUANTITIES OF SUGAR IN URINE.

By J. SEEGEN, M.D., Professor in the University of Vienna.

TROMMER'S is the most reliable and delicate test for sugar. With its aid, I am able with certainty to make out 0.3 milligramme (0.0046 grain) of sugar dissolved in 10,000 times the amount of fluid. This great delicacy of

the test, however, only holds good as long as we have to do with a watery solution of sugar. If, on the contrary, small quantities of sugar are to be detected in urine, Trommer's test is neither delicate enough nor reliable, for two reasons. (1). Urine contains certain substances (colouring matters, creatine) which prevent the suboxide of copper when formed from being precipitated; no separation of the reduced suboxide of copper, therefore, takes place, the blue fluid only becoming yellow or yellowish brown, or presenting a turbid discolouration. (2). The same processes of reduction are also brought about by uric acid; and urine containing a considerable amount of uric acid acts on Fehling's test-fluid exactly in the same manner as urine containing 0.1 to 0.2 per cent of sugar.

The method devised by me has for its object the exclusion of those other constituents of urine which would disturb the proper action of the test, and the transformation, as it were, of the saccharine urine into a watery solution of sugar. Animal charcoal has the property of retaining most of the constituents of urine, more especially the colouring matters and uric acid. After filtering a watery solution of uric acid through animal charcoal I could (provided the charcoal had been good), after repeated filtrations, not find a trace of uric acid in the filtered fluid. Now, in order to detect small quantities of sugar in urine, I proceed in the following manner.

I filter one or two ounces of the urine several times through good animal charcoal until the urine is completely colourless. This operation only takes a few minutes. Then I wash the charcoal on the filter with a little distilled water, and to this water, when filtered off, I apply Trommer's test. The water with which the charcoal has been washed is almost as sensitive to Trommer's test as a watery solution of sugar, and in it I could detect even 0.01 per cent of sugar by a beautiful red precipitate of suboxide of copper, whilst the original saccharine urine, when not filtered, only produces a yellow discolouration of Fehling's test-fluid. With urine containing a little more sugar—say, 0.1 to 0.2 per cent—the water flowing off from the second and third washing acts even more energetically upon the test-fluid than that of the first washing, producing an even purer deposit of suboxide of copper. The water obtained by the subsequent washings thus evidently contains the sugar in a purer form. With normal urine, the water obtained by the above process is either entirely inactive towards Fehling's test-fluid, which remains blue, or it assumes only after a while a slight dichroid (varying colour according as the light falls on or passes through) turbidity. The water obtained by a second and third washing always remains without any effect. When the quantity of sugar has to be determined, the urine must not be filtered through charcoal, as the latter always retains a certain quantity of the sugar which cannot be removed again by washing.—*British Medical Journal*.

NOTICES OF BOOKS.

A Series of Chemical Labels for Use in Laboratories, &c.
Published by Mottershead and Co., 1, Market Place, Manchester.

WE notice this book of labels because it supplies one of the chief wants of the laboratory—a label clearly printed and having no peculiarity. The common names have been adhered to, prefixes and suffixes being employed only when absolutely necessary; no symbols are attached, but space has been left for the chemist to write them according to his own views. The labels for substances in common use are in duplicate, while the adjective terms "Pure," "Commercial," &c., are provided upon separate slips. We recommend these labels to the notice of every chemist.

CORRESPONDENCE.

THE EVIDENCE OF EXPERTS.

To the Editor of the Chemical News.

SIR,—In your valuable paper there has recently appeared an article entitled "The Evidence of Experts" republished from the *Scientific American*, which, through an erroneous statement, implies an injurious reflection upon several eminent gentlemen. For this reason I trust you will, in the interest of fair play, give room for this brief correction. Had the mis-statement not found its way into a foreign journal it would have been unnecessary to refer to it, since it is part of the history of a chemico-legal investigation in a recent poisoning case, which, while in progress, excited so much attention that every newspaper-reading person in this country is familiar both with the result of the chemical testimony and the names of the experts involved.

The article opens as follows:—"In Philadelphia we have had recently the spectacle of a professed chemist and toxicologist making an examination of the body of a man supposed to be poisoned, and carrying his investigation far enough to convince himself of the presence of antimony; and, forgetting that there was a jury and a public to convince as well, appearing on the witness stand without a particle of proof that he found it except his bare assertion," &c.

The statement that this case (which is none other than the celebrated Wharton poisoning case, tried at Annapolis, Maryland) was tried in Philadelphia is untrue, and the inference which one unfamiliar with this fact must draw, upon reading the sentence, is plainly that a Philadelphia chemist "afforded the spectacle," &c. The injustice of this inference will be apparent when I state that the person affording the spectacle was a citizen of Baltimore; and that the share which Philadelphia chemists had in the case was the honourable one of exposing the untrustworthiness of a bungling analysis, and thus securing the acquittal of the prisoner.—I am, &c.,

WILLIAM H. WAHL.

Franklin Institute, Philadelphia,
May 20, 1872.

WATER ANALYSIS.

To the Editor of the Chemical News.

SIR,—In your paper of the 15th March, I notice a letter from Assistant-Surgeon Nicholson, in which he states that the analyses which have been made during the past four years of the waters of military cantonments in Bengal were made upon a method drawn up in neglect of the peculiarities of Indian waters, and that, in consequence, the results were in most cases erroneous, and, from a chemical point of view, worthless. I might simply meet this assertion by another, namely, that the method which was employed was directed, so far as needful, to the case of Indian waters, and that as, when I drew up the scheme, I had been engaged in analysing Indian waters for over fifteen years, I knew very well what those peculiarities are. I might also add that the reports of the analysts who used this method, which have been included in my reports to the Government of India on the subject of the analysis of potable waters, have gained the marked approval of the Army Sanitary Commission, as well as of Dr. Parkes and Dr. Angus Smith.

The peculiarities to which Dr. Nicholson specially refers are the frequent presence in Indian waters of a large quantity of nitrates in a sample which is free from organic matter, and *per contra* of water contaminated with sewage containing little or no nitric acid. These, however, are facts which have been not only recognised

by me, and by analysts who have worked under my guidance, but also by Dr. Angus Smith, who, in a pamphlet which he wrote upon the subject,—one, by the way, to which I was much indebted in drawing up a scheme for use in Bengal,—drew attention to these very points, and urged their consideration upon those engaged in water analysis. I should hope that no one would think of condemning a water simply because it contained a large quantity of nitrates or of chlorides, though he would do well to remember that, under some circumstances, if positive, the presence of either in any quantity would be a warning not to be despised.

I willingly allow that the scheme of analysis of potable waters which I drew up six years ago, for the use of our water analysts, needs great modifications; but these have been introduced in the revised scheme which, in communication with Dr. Angus Smith and Dr. Parkes, I compiled under instructions from the India Office, when I was lately on furlough. This more recent scheme includes the admirable methods of water analysis introduced by Messrs. Wanklyn and Chapman. I may, however, say that the old scheme was very much modified by me in communication with the individual analysts, and in particular Messrs. Wanklyn and Chapman's processes were introduced so far back as 1868.

While carrying out the analysis of the potable waters of Bengal and adjacent Presidencies, I had to bear in mind that our analysts were not for the most part trained chemists; and, therefore, to have asked from them complete analyses of the mineral constituents of water would have been, for more reasons than one, a very unwise proceeding. Nor do I think that such analyses are generally needful; and I may conclude by saying that if I were now instructed by Government to do over again the work lately done in Bengal, I should feel much inclined to put into the hands of the analysts Messrs. Wanklyn and Chapman's work on water analysis, with instructions to work by it, supplementing the chemical with a microscopical examination of the waters, and charging them, as I have always done, to bear in mind that by no method of analysis can we with certainty detect all dangerous matters in a water, while, however, we may with certainty exclude danger by strict attention to the sanitary condition of the water source.—I am, &c.,

F. N. MACNAMARA, M.D.

(Surgeon Indian Army, Chemical Examiner
to the Government of India).

Medical College, Calcutta,

ATOMIC THEORY.

To the Editor of the Chemical News.

SIR,—It is evident that "An Aggrieved Atom" is labouring under a misconception of the statements made in the paper referred to. A little thought would have shown him that Whately's definition does not apply to the law of multiple proportions, seeing that the several instances do not "exhibit a conformity to that statement."

It is a very common saying, that the law of multiple proportions is a fact which will remain as one of the bulwarks of the science, whatever becomes of the atomic theory; but nothing is more certain than that the so-called law is completely dependent upon that theory. By the examination of some simple bodies, such as carbonic oxide and carbonic acid, olefiant gas, and marsh gas, Dalton obtained results which led him to think that the elements combined in multiple proportions; but his analyses were further from the theoretical numbers than those now obtained, although the latter do not lead to that law. These discrepancies are overlooked by the use of the atomic theory, but without that theory no law of multiple proportions does exist.—I am, &c.,

R. W. ATKINSON.

University College Laboratory,

MISCELLANEOUS.

Chemical Society.—On Thursday last, May 30th, Professor Cannizzaro, of Palermo, delivered the "Faraday Lecture" before a large audience, including a number of ladies. The Lecture Theatre of the Royal Institution had been kindly lent to the Chemical Society for this purpose, and we hope in our issue of next week to be able to lay before our readers a tolerably full abstract of the learned Professor's discourse, entitled "Considérations sur quelques Points de l'Enseignement Théorique de la Chimie." On Friday a dinner was given to the Professor, at which about 150 were present, including the Italian Ambassador and the Right Hon. the Chancellor of the Exchequer.

Improved Blowing Apparatus for Blowpipe Operations.—The *Berg-und-hüttenmännische Zeitung* contains the following description of an improved blower, by Messrs. Armin, Junge, and K. Mitzopoulos, of Freiburg. All workers with the blowpipe are well aware how much the work is facilitated by a good blowing apparatus. In qualitative operations it can be dispensed with, but there are certain assays—such as concentrating cupellations for poor silver ores—which cannot be carried on without a blower, save with great exertion. For this reason, nearly every one who has quantitative assays to make provides himself with a blowing apparatus. The ordinary blowing apparatus consists of three parts,—the caoutchouc bellows, the regulator, and the stand for the nozzle. The part which most easily gets out of repair is the caoutchouc regulator, for the operator, looking at his assay, often does not perceive how the regulator gets too much stretched by the blast; the consequence is that the regulator often bursts. When we recollect that such regulators are not to be had everywhere, and that a reserve stock is often useless, from the caoutchouc getting hard, it becomes important to find a substitute which will give as regular a blast and can be made of a more lasting material. It is this that we have had in view in making our regulator, and we will proceed to explain its mode of construction for the benefit of those who might happen to want one. Our regulator gives a perfectly constant blast, which can be used either for the oxidising or the reducing flame, and, after numerous trials, we can say that it is in no way inferior to the caoutchouc regulator. At the same time it is so simple that it can be constructed with great ease, and in a very short time. The arrangement is as follows:—A common wide-mouthed bottle is carefully fitted with a caoutchouc cork bored with two holes, into each of which passes a piece of glass tube bent at a right angle. On to one of these tubes is slipped the caoutchouc tube coming from an ordinary caoutchouc bellows, whilst the other is put in communication with the blowpipe nozzle by means of four pieces of caoutchouc tubing joined by three pieces of glass tube, drawn to a fine point at each end. This forms the main peculiarity of the arrangement. When air is forced into the bottle by the blower, in jerks, it finds a difficulty in escaping as fast as it comes in, on account of the six fine openings in the glass tubes that it has to pass through on its way from the bottle to the nozzle, and it thus acquires a certain pressure in the bottle, and flows out towards the nozzle as a regular blast. The bottle may be about 6 inches high by 3½ inches wide, with a neck 1½ inches in diameter; but of course the dimensions are of no great importance. On the whole a somewhat large bottle is better than a small one. The pieces of glass tubing we use are 2 inches long by ¼ of an inch in diameter. The apparatus will be stronger if instead of a glass bottle a tin cylinder is used, about 4 inches high by 2 inches in diameter, with two tin tubes opening into its top. Small metal cylinders, with a fine hole at each end, may be used instead of the little glass tubes. A blowing apparatus constructed in this manner will deliver a perfectly regular blast, and will be of practical interest to those who are thinking of working

in places where it is difficult or impossible to repair the ordinary instruments.

Oxygen and Oxyhydrogen Gas.—A lively discussion is going on, in scientific and other circles, relative to MM. Tessié du Motay and Co.'s proposals for applying oxygen gas to the lighting of streets and houses, and also to manufacturing purposes. M. Tessié du Motay's process has been public for some time. It consists, in a few words, of charging elliptical retorts each with 300 kilos. of a mixture composed of 3 parts of manganate of soda and 1 part of oxide of copper intimately blended together. Those retorts are said to yield each 35 cubic metres of oxygen gas in eight operations, each occupying three hours. Eight such retorts are in working order at the Company's Works at Pantin. A steam-engine of 20 horse-power nominal is used to inject compressed air into the retorts, to compress the gas in the cylinders, and to supply the necessary steam for the disengagement of the oxygen. The applicability of the mixed gases to lighting purposes is discussed with much asperity, but this may be attributed in part to objections of the Gas Company which supplies all Paris, and naturally is tenacious of its monopoly. MM. Tessié du Motay and Co. have, however, applied to the Municipal Council of the city for permission to lay down mains and supply-pipes for the distribution of oxygen, and it is believed that the application will be acceded to. The price of the gas is also fiercely disputed. On the one hand, it has been declared that the actual working cost is not more than 15 centimes the cubic metre, while, on the other hand, it is asserted that it cannot be sold at a profit at a lower rate than 1f. 70c. the cubic metre: the Tessié du Motay Company would seem to have settled this latter question, by issuing a public notice, to the effect that as soon as the mains and pipes can be laid down, oxygen gas will be sold to the public—either for lighting purposes, the smelting of metals, or other manufacturing purposes, and, above all, for the purification of the air in houses and hospitals—at a price not exceeding 1 franc the cubic metre, the Company taking upon itself the entire cost of the necessary means of supply. The subject is one of great interest, and as M. Tessié du Motay and his partners ought certainly to know what their products cost, there seems a fair probability that pure oxygen will be placed at the disposition of the manufacturer at a moderate cost. The application of this gas to business purposes seems far more promising than that of its general use in street or house lighting. The necessity for two sets of pipes and two meters, one for each of the gases, and the nicety required in regulating their proportions, are likely to present considerable difficulties in practice.—*Journal of the Society of Arts.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, April 29, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Researches on Crystalline Dissociation.—P. A. Favre and C. A. Valson.—The second instalment of an exhaustive monograph on this subject, elucidated by a series of tabulated forms exhibiting results of experiments.

Constitution of Clay.—P. de Gasparin.—The author communicates the analysis of a sample of clay taken from the plain of the Vistre not far from Nîmes (Département du Gard), this soil being noted for its great fertility. The results of the physical analysis are, in 100 parts—Stones, 2.85; sand, 50.35; matter impalpable and soluble in water, 47.80. Chemical analysis, in 100 parts—Insoluble in nitro-hydrochloric acid, 58.96; soluble in nitro-hydrochloric acid—Carbonate of lime, 27.84; carbonate of magnesia, 0.89; potassa, 0.225; soda, 0.105; peroxide of iron, 4.35; alumina, 2.03; water of combination, 1.45; phosphoric acid, 0.146 (this is equivalent to 6 tons per hectare of surface of the land); organic matter, 4.004.

Absorption-Spectra of the Vapours of Selenium, Protochloride and Bromide of Selenium, of Tellurium, Protochloride and Protobromide of Tellurium, of the Protobromide of Iodine, and of Alizarine.—D. Gernez.

Study on the Salt-Making Industry of Portugal.—A. Girard.—This paper treats exhaustively on the mode of obtaining salt from sea-water by spontaneous evaporation, as practised in the salt-gardens of a certain district of Portugal, whereby the so-called sea-salt is obtained.

Presence of Selenium in Sulphuric Acid Made in France.—I. Personne.—It appears that the sulphuric acid obtained from a manufactory near Paris, and made from a copper-containing pyrites of French origin, contains 0.2 grm. of selenium in 3 litres of acid. As to the source whence this selenium is derived, the author is inclined to ascribe it to the pyrites used in the preparation of the acid. Sulphuric acid made from Belgium pyrites at the same works was found not to contain any selenium. The author is engaged in making further researches on this subject.

Action of Oxygen upon Certain Vegetable Infusions.—L'Abbé Laborde.—This paper contains the detailed description of an experiment made with the view to prove that active oxygen (ozone) is incapable of calling forth fermentation under the conditions alluded to.

Question of the Assimilation of Ammonia by Yeast.—Dr. Griesmayer.—After referring to some discussions which have taken place recently on this subject, the author calls attention to the fact that the ammonio-phosphate of magnesia, when boiled either along with some water and calcined magnesia or even with water alone, gives off its ammonia, which is in a short time completely expelled.

We quote the titles of the two following papers, although the subjects treated of do not precisely belong to chemistry:—

Sanitary Police in reference to Rinderpest.—Dr. Bouley.—The condensed report of the proceedings of the international conference which lately held its meetings at Vienna.

Human Skeleton Found on March 26 in the Caverns of Baoussé-Roussé (Italy) Known as the Grotto of Menton.—E. Rivière.

May 6, 1872.

This number contains the following original papers relating to chemistry:—

Process of Decorative Painting upon Tinfoil.—C. Daniel.—The detailed description of a method of painting with oil paints upon tinfoil stretched uniformly on sheets of plate glass until the painting and varnishing are finished. The tinfoil thus prepared is used instead of paper-hangings, and for decorative purposes; gilding can also be applied.

Light Emitted by the Vapour of Iodine.—G. Salet.—When a crystal of iodine is put into a hard glass tube, the tube sealed, and then strongly heated to redness at some distance from the iodine, the latter substance will be seen, after the heating of the tube has been discontinued, to become volatilised, and to exhibit when entering the still hot portion of the tube a brilliant red light. This experiment may be also made by means of a glass tube provided with a spirally-wound platinum wire, which is made red-hot by means of an electric current.

Conversion of Pyro-Phosphates into Phosphates.—M. Prinvault.—When boric acid is fused along with pyro-phosphate of soda, and the fused mass taken up with water, there is formed ordinary phosphate of soda; the pyro-phosphate of soda has thus absorbed an equivalent of water of constitution by the action of the boric acid. It is, the author thinks, probable that phospho-borate of soda is formed, which is decomposed by the water into boric acid and ordinary phosphate of soda. The action of sulphuric acid, when converting pyro-phosphate of soda into ordinary phosphate of soda, is explained by the author as due to the formation of an alkaline phospho-sulphate.

Quantitative Estimation of Copper by Means of Cyanide of Potassium.—M. Yvon.—The author, first referring to De Lafoleye's paper on this subject, asserts that the author just named is not the discoverer of this process. M. Yvon quotes a paper on the subject, published as far back as 1859, by Buignet (*Bulletin de l'Académie de Médecine et Journal de Pharmacie et de Chimie*, third series, vol. xxv., p. 168). The author (Yvon) further observes that De Lafoleye's assertion that the presence of iron or zinc does not interfere with the operation, is quite incorrect, since he (Yvon), who has been engaged since January last in trying to make Buignet's plan practically available, has not as yet surmounted the difficulty which the presence of these metals places in the way of making the otherwise good plan practically useful. The author continues his researches, and intends to publish a complete account thereof.

Formation of Diphenylamine.—Ch. Girard and G. de Laire.—The authors first refer to their paper, published in the *Comptes Rendus*, of 18th March last (see CHEMICAL NEWS, No. 646, April 12, 1872, page

178), and then state that, since their experiments, made according to the directions given by Dusart and Bardy, do not agree in the results obtained with those obtained by the last-named parties. They (Girard and De Laire) request that the Academy may appoint a committee to verify these matters.

This number further contains several important papers and memoirs relating to geology, paleontology, meteorology, physiology, and natural history.

Le Moniteur Scientifique Quesneville, No. 364, April, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

On Smells according to the most Recent Chemical and Physiological Discoveries.—F. Papillon.—This excellent essay, too lengthy and too concisely written for any useful abstraction, contains a large and well-digested amount of information, and is elucidated by historical details of importance.

Anthracen and its Derivatives.—Dr. E. Kopp.—The continuation of this lengthy monograph. This portion treats on the action of sulphuric acid upon bichloro-anthracen, $C_{14}H_2O_2$; action of sulphuric acid upon bibromo-anthracen, $C_{14}H_2Br_2$; preparation of alizarine; details of English patents and French *brevets*; on the state in which alizarine is found in madder. To be continued.

Use of Silicate of Soda in Soap-Making.—G. Schnitzer.—This paper contains a valuable amount of practical information relating to soap-boiling by the so-called cold process.

Manufacture of Tartaric Acid in South Germany.—Dr. Kurz.—This memoir is divided into the following chapters:—Preparation of tartrate of lime, (a) by means of argol, and (b) by means of ley of wine; treatment of the humid wine-yeast; treatment of dry wine-yeast (residues of wine-fermentation); separation of the tartaric acid from the tartrate of lime; refining of argol; estimation of the value of argol.

Bibliography.—"L'Électricité Appliquée aux Arts Mécaniques, à la Marine, au Théâtre," par M. E. Saint Edme; 1 vol.; Paris: Gauthiers-Villars. It appears from the review here quoted that this is a very interesting work.

American Journal of Pharmacy, May, 1872.

In addition to several excellent papers and memoirs more particularly bearing upon pharmacy and pharmacognosy, this number contains the following original papers relating to chemistry:—

Lycopersicum Esculentum, Tomato.—T. D. McElhenie.—This paper contains the very detailed account of a series of experiments made with the fruit alluded to mainly for the purpose of ascertaining the nature of the acids present in this fruit; these acids are citric, oxalic, malic, and tartaric, the latter, however, only in very small quantity.

Yaupon.—H. M. Smith.—Under this name the Indians indicate the leaves of the *Ilex Cassine*, a plant indigenous to some parts of the southern States of the Union; these leaves, mixed with those of other species of the same plant, *Ilex vomitoria* and *Ilex dahoon*, form the cassena, the basis of their (Red Indians) famous black drink, used as medicine and as a state drink at some of their religious festivals. The constituents of the yaupon are per centually—Volatile oil, 0.011; wax and tar, 0.466; resin, 3.404; chlorophyll, 2.491; caffeine, 0.122; tannic acid, 4.814; gum and pectin, 8.244; extractive matter, 10.149; starch, pectose, &c., 15.277; nitrogenous matter, 8.138; woody fibre, 3.854; moisture, 7.595; ash, 3.935; total, 101.939. Yaupon is largely used in the southern States as a substitute for tea, coffee, and other stimulants, and is reported to be very beneficial to inebriates who wish to cure themselves of their love of liquor.

Ether Glue.—Dr. J. M. Maisch.—An excellent liquid glue is made by dissolving glue in nitric ether; this fluid will only dissolve a certain amount of glue, consequently the solution cannot be made too thick. The glue solution obtained has about the consistency of molasses, and is doubly as tenacious as that made with hot water. If a few pieces of caoutchouc, cut into scraps the size of buckshot, be added, and the solution allowed to stand a few days, being frequently stirred, it will be all the better, and will resist dampness twice as well as glue made with water.

La Revue Scientifique de la France et de l'Etranger, May 4, 1872.

This number does not contain any original papers bearing on chemistry, but we call attention to the titles of the following papers:—

Superior Agricultural Instruction at the Ecole Centrale des Arts et des Manufactures at Paris.—J. Dumas.—This excellent essay contains a clearly written *exposé* of the means adopted in France for giving instruction in agriculture, practical as well as theoretical.

Continuation of the Lectures on Animal Heat.—C. Bernard.

May 11, 1872.

This number, also, does not contain any original papers bearing on chemistry, but we notice:—

Scientific Journey to Madagascar.—A. Grandidier.—This essay, illustrated with a map, contains some very valuable and reliable information concerning an island which is considerably

larger than France, even before the late war, Madagascar having a surface of 590,000 square kilometres.

The Mineral Waters of France.—Dr. Gubler.—An excellent therapeutic essay, from which it appears that the country just named contains most valuable mineral sources, thermal as well as cold, of various kinds.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
March 21, 1872.

Studies on the Dynamometers.—Dr. C. Mène.—The first instalment of a treatise on this subject, illustrated with woodcuts.

Volumetric Quantitative Estimation of Lead.—M. Buisson.—This process is based upon the precipitation of lead by means of bichromate of potassa, and the subsequent complete decomposition of this reagent (used in excess) by iodide of potassium in a liquor acidulated with sulphuric acid. The iodine set free is next estimated by starch and hyposulphite of soda. Although this process yields reliable results with nearly pure lead, many metals interfere with its correctness, as, for instance, silver, bismuth, copper, baryta.

Estimation of Water in Animal Charcoal.—Dr. Walz.—From a series of experiments made by the author, he comes to the conclusion that a weighed sample of animal charcoal, such as is used in sugar refineries, when exposed for an hour to a temperature of 250° F., is completely dried; a higher temperature should be avoided, since then, probably owing to oxidation, an increase of weight is observed. Animal charcoal, though apparently dry, may absorb as much as 15 per cent of water, and usually contains about from 5·5 to 7 per cent of moisture.

March 28, 1872.

Under the title—

Actualités.—Dr. C. Mène.—This number opens with the first instalment of a discussion on fermentation, decay, catalytic force, and ferment.

Absorption of Metallic Salts by Mordanted Woollen Fabrics.—P. Havrez.—This paper, not well suited for any useful abstraction, contains some very important results of researches relating to the practice of mordanting.

Description of a Newly-Devised Apparatus for the Economical Manufacture of Illuminating Gas.—M. Martin.—This contrivance is specially arranged for making gas from either liquid or solid volatile hydrocarbons, which are first, in a special vessel, volatilised under high pressure, and the vapours next converted into gas by passing them through a red-hot retort filled with lumps of coke. The apparatus, illustrated by a woodcut, can be placed in a kitchen, and is especially made for use in isolated houses and country places situated at a distance from large gas-works.

Les Mondes, May 2, 1872.

French Association for the Advancement of Science.—The inaugural meeting of this Association has been held under the presidency of Dr. C. Bernard, assisted by MM. Dumas, Wurtz, and Broca. After the approval of the statutes which rule this Association, an inaugural discourse was delivered by Dr. Wurtz. This newly-organised institution is akin, in its scope and arrangements, to the British Association for the Advancement of Science. In some French town or city the Association will hold a meeting annually, while it is also intended to advance science by other means.

Preparation of Caustic Soda by means of Sulphuret of Sodium.—Tessié du Motay.—The author distinguishes between processes by the dry and the wet way. The former is described as follows:—When one equivalent of sulphuret of sodium is mixed and fused with one equivalent each of caustic soda, hydrate of lime, and metallic iron (either cast or malleable), and these substances heated to redness, the sulphuret of sodium is completely converted into caustic soda, while sulphuret of iron is simultaneously formed. This reaction is explained by the author as follows:—The water of the hydrate of soda, or of the hydrate of lime, is decomposed by the iron which becomes oxidised, hydrogen is set free, oxide of sodium formed, and next sulphuret of iron; the soda is separated from the last-named substance by lixiviation with water. As regards the process by the wet way, the author converts the sulphuret of sodium into a basic phosphate of soda by means of a rather circuitous process (scientifically correct, but not well adapted for industrial application), and this basic phosphate of soda is next converted into caustic soda by means of caustic lime.

May 9, 1872.

Pathologico-Chemical Laboratory.—The Municipal Council of Paris has made the necessary arrangements to construct a pathologico-chemical laboratory to be added to the School of Practical Science established in that city.

Electro-Magnetical Apparatus for Medical Use and Physiological Applications.—MM. Trouvé and Onimus.—The detailed description illustrated by woodcuts of very ingeniously-contrived and well-arranged electro-magnetical apparatus, especially suited for medical use and physiological experiments.

Preservation of the Wood of Telegraph-Poles in Norway.—F. Michel.—The property of freshly cut down trees of continuing the circulation of the sap is made use of to cause the wood (fir trees) to absorb sulphate of copper, introduced into holes some 16 to 18 centimetres in depth, and closed by wooden plugs or corks coated with tar or varnish. The introduction of sulphate is repeated two or three

times a year for a period of two or three years, during which time the poles absorb a sufficient quantity of sulphate of copper to prevent the wood from decay for ten to twelve years in the climate of Norway, where the winters are very severe, but comparatively dry.

May 16, 1872.

This number has not yet been received.

May 23, 1872.

Atelier de Silex Préhistoriques.—E. Lejeune.—The author states that he has discovered, in a secluded locality, Escalles (Pas-de-Calais), a workshop, wherein, aided by excellently-constructed machinery and well-made tools, pre-historic silex and quartz implements are made on the large scale, the workshop being situated in the neighbourhood of a number of tumuli.

Submarine Hydro-Electric Cable.—Rev. F. Moigno.—A preliminary notice of an invention made by F. Tommasi, whereby it is stated that telegraphic submarine communication can be obtained without the use of the ordinary electric cables, and at greatly lessened cost and very much increased rapidity of transmission of signals.

Wood-Carving by Machinery.—H. A. Lanteigne.—The description, illustrated by a woodcut, of an apparatus for carving wood.

Bibliography.—Under this heading we meet here with an exhaustive review of the work just published:—"La Création du Monde organisé d'après les Naturalistes Anglais et Allemands," par M. Charles Martins, Professeur de Botanique à la Faculté des Sciences de Montpellier.

Petites Annales de Chimie.—Dr. Maumené.—The continuation of a series of papers on chemical philosophy.

May 30, 1872.

This number only contains the index for the first four months of this year.

MEETINGS FOR THE WEEK.

MONDAY, June 10th.—Royal Geographical, 8.30.

London Institution, 4. Prof. Bentley, F.L.S., "On Elementary Botany."

TUESDAY, 11th.—Civil Engineers, 8.

Photographic, 8.

THURSDAY, 13th.—Royal, 8.30.

Royal Society Club, 6.

FRIDAY, 14th.—Astronomical, 8.

Quekett Club, 8.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that *Subscribers in the United States* can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of Six dollars or £1 2s. 4d. per annum payable in advance.

NEW WORK BY PROFESSOR TYNDALL.

On Tuesday, June 11, in One Volume, 8vo.,

Researches in Molecular Physics by means of

Radiant Heat: a Series of Memoirs collected from the "Philosophical Transactions." By JOHN TYNDALL, LL.D., F.R.S., Professor of Natural Philosophy in the Royal Institution of Great Britain.

London: Longmans, Green and Co., Paternoster Row.

In One Volume, 8vo., with Woodcuts, price 7s. 6d.,

A Manual of Chemical Physiology, including its Points of Contact with Pathology. By J. L. W. THOMPSON, M.D.

London: Longmans, Green, and Co., Paternoster Row.

Nearly Ready, Fifth Edition,

A Plea for Reflectors. Being a description

of the new Astronomical Telescopes with Silvered Glass Specula, and instructions for adjusting and using them, and Silvering Glass Specula; with full page Chromo-Lithograph of Jupiter, and numerous Illustrations, additional matter, and a simple method of adjusting an Equatorial. By JOHN BROWNING, F.R.A.S., M.R.I., &c., &c. Price 1s.

Also, Nearly Ready,

An Illustrated Descriptive Catalogue of SPECTROSCOPES and SPECTRUM APPARATUS, with Chromo-Lithographic Chart of Spectra, and Appendices, How to use a Spectroscope, a Micro-Spectroscope, a Tele-Spectroscope, and Screen Spectrum Apparatus. Price 1s. 6d., post free. JOHN BROWNING, Optical and Physical Instrument Maker to the Royal Observatory, &c., &c. 63, Strand, W.C., and 111, Minorica, E. Price Medal, 1862. Established 100 years.

THE CHEMICAL NEWS.

VOL. XXV. No. 655.

ON THE SEPARATION OF PHOSPHORIC ACID, FERRIC OXIDE, ALUMINA, LIME, AND MAGNESIA.*

By THOMAS ROBERTSON OGILVIE, F.C.S.

To separate and accurately estimate phosphoric acid, ferric oxide, and other bases, is one of the most difficult problems in analysis. It is also of great commercial importance, on account of the large quantities of ferruginous phosphatic minerals employed in the manufacture of superphosphate of lime: besides, owing to the increased demand of late for these minerals, they have considerably advanced in value, and merchants now ask from analysts a greater delicacy and minuteness of detail in their results than formerly. Another reason why a correct and speedy method of separation is of consequence has just been clearly shown by a member of this section, in the prominent part which ferric oxide and alumina play in the manufacture and composition of artificial manures.†

The method generally recommended is to dissolve the mineral in acid, evaporate to dryness, filter from the siliceous matter, precipitate the lime as oxalate, which, after being washed, dried, and ignited, is weighed as carbonate. The filtrate is evaporated to a small bulk, citric acid added to hold up the ferric oxide and alumina, and the phosphoric acid separated as ammonio-magnesian phosphate. To the fluid from this precipitate is added some nitrate of potash and sufficient carbonate of soda to effect the decomposition of the chloride of ammonium, the whole brought to dryness, and ignited, so as to decompose and remove the citrate and other ammoniacal salts. The residue is dissolved by digestion for some time in acid, and the ferric oxide and alumina are precipitated in the usual way. The magnesia, which is present in mineral phosphates in very small quantities, is determined in another portion of the acid solution by separating the lime with oxalate of ammonia, the ferric oxide and alumina with ammonia and acetic acid, and then allowing the filtrate—which contains a large quantity of phosphoric acid—to stand till the magnesia separates as ammonio-magnesian phosphate.

This plan of estimation is objectionable on two grounds:—first, because phosphoric acid cannot be estimated with accuracy in presence of oxalate and citrate of ammonia, if they exist in any considerable quantity; and second, because the removal of the chloride of ammonium and the decomposition of the other ammoniacal salts are tedious and troublesome operations.

Another method of separating ferric oxide and alumina is that given by Warington, in his excellent paper on "The Analysis of Mineral Phosphates."‡ To the acid solution of the mineral large excess of caustic soda is added, which gives a precipitate of ferric oxide and phosphate of lime. The iron may be estimated by the permanganate process, or separated from the phosphate of lime by dissolving in hydrochloric acid, precipitating with ammonia, and adding large excess of acetic acid, which leaves the iron as phosphate. It will contain a little lime, which may be removed by re-dissolving and re-precipitating. The filtrate from the ferric oxide and phosphate of lime contains the alumina,

and is treated with chloride of barium to remove phosphoric acid, with carbonate of soda to separate the excess of baryta, and then with ammonia to precipitate the alumina. This mode of determining the oxides has not come into frequent use, owing to the great deal of manipulation involved, and because of the difficulty of obtaining caustic soda free from alumina.

About a year ago our leading agricultural chemists began to adopt Sonnenschein's method of separating phosphoric acid as phospho-molybdate of ammonia; and since then the extraordinary discrepancies previously so frequent have to some extent ceased. Regarding this process Warington, in the paper already quoted, states that "it is inadmissible, from the large amount of phosphoric acid to be determined" in mineral phosphates: and Fresenius says that "the phosphoric acid in the substance taken to operate upon should not be allowed to exceed 0.1 grm.,"* which would be equivalent to about 0.3 grm. of the mineral, a quantity so small that few chemists would care to work upon it in ordinary commercial analysis. Watts also repeats these statements: he says "it cannot be depended upon for giving exact results, excepting when the quantity of phosphoric acid to be determined is very small."† I have thoroughly satisfied myself, however, by a number of experiments, that perfectly satisfactory results may be got by employing a quantity of the substance containing even 0.3 grm. of phosphoric acid. We may therefore separate the phosphoric acid in such minerals as apatite, coprolite, Rhenish phosphorite, and South Carolina phosphate, by this highly-accurate method, and in the filtrate from the phospho-molybdate of ammonia determine the bases.

Before referring to the latter point, which is the more immediate subject of this paper, I shall briefly give the details of Sonnenschein's process.

(a). *Separation of Phosphoric Acid as Phospho-Molybdate of Ammonia.*—Five grms. of the finely-ground mineral are dissolved in nitric acid, evaporated to dryness so as to render any soluble silica insoluble and avoid its interfering with the subsequent determination of the bases, re-dissolved in the same acid, filtered from the siliceous matter, and the filtrate made up to 250 c.c. The siliceous matter should be free from ferric oxide; if not, it must be digested in strong acid until it becomes white, and the solution added to the original filtrate. Of the fluid 50 c.c., containing 1 grm., are transferred to a beaker, a sufficient quantity of molybdenum solution added, and the whole allowed to stand—at a temperature of 40° C.—until the precipitate thoroughly subsides, for which four hours are generally sufficient. The molybdenum solution is prepared in the following manner:—10 grms. of molybdate of ammonia are dissolved in 40 c.c. of ammonia (0.96 sp. gr.), heat applied gently, then 160 c.c. of a mixture of equal parts of nitric acid and water added, care being taken to keep down the temperature. In this way a solution of known strength is got, and little difficulty will be experienced in using the requisite quantity, namely, 40 parts of molybdic acid for every 1 part of phosphoric acid present. The phospho-molybdate of ammonia is filtered, washed with a mixture of equal parts of the molybdenum solution and water, then dissolved in ammonia, and, after neutralising the greater part of the free alkali with hydrochloric acid, "magnesia-mixture" added in slight excess and the phosphoric acid precipitated as ammonio-magnesian phosphate.

The filtrate from the phospho-molybdate of ammonia will contain all the bases as nitrates, and Fresenius‡ gives the following plan of separating them from the molybdic acid:—Mix the acid fluid in a flask with ammonia to alkaline reaction, add sulphide of ammonium in sufficient excess, close the mouth of the flask, and digest the mixture. As soon as the solution appears of a reddish-yellow colour, filter off the fluid which contains sulphide

* Read before the Glasgow Philosophical Society, April 29, 1872.

† Watts's "Dictionary," vol. iv., p. 546.

‡ "Quantitative Analysis," 4th ed., p. 285.

of molybdenum and the alkaline earths, wash the residue of sulphide of iron and alumina with water containing a little sulphide of ammonium, and determine the oxides by the usual methods. The sulphide of molybdenum is next precipitated from the filtrate with hydrochloric acid, and the lime and magnesia estimated in the filtrate. But such a process is too troublesome and protracted for ordinary use, and I propose to render it more simple and expeditious, by taking advantage of the well-known property of molybdic acid of remaining in solution in presence of free alkali, and determining the bases in its presence.

(b). *Separation of Ferric Oxide and Alumina.*—The filtrate from the precipitate of phospho-molybdate of ammonia, consisting of a nitric acid solution of molybdic acid, ferric oxide, alumina, lime, and magnesia, is placed in a beaker, and cautiously neutralised with ammonia, care being taken that the temperature does not rise above $40^{\circ}\text{C}.$, and that the alkali is added only in slight excess; allow to stand in a warm place until the precipitate completely settles, filter the clear supernatant fluid, wash the precipitate by decantation, then transfer it to a filter, and finish the washing. Next, re-dissolve the precipitate in weak nitric acid, re-precipitate, and wash in the same careful manner. If the filtrate is found to contain any lime it is added to the original solution. The precipitate is dried, ignited, and weighed as ferric oxide and alumina. By re-dissolving in hydrochloric acid the former is rapidly determined, after reduction with zinc, by Penny's bichrome process, and the latter found by difference.

(c). *Separation of Lime.*—The alkaline filtrate from the ferric oxide and alumina is treated with oxalate of ammonia, and allowed to stand in a warm place, until the precipitate of oxalate of lime has completely subsided, which will take place in about three hours. The clear fluid is then filtered, the precipitate washed by decantation and otherwise, dried, and ignited; care being taken that no caustic lime is formed.

(d). *Separation of Magnesia.*—To estimate the magnesia in the solution from the oxalate of lime, the ammonia salts must be removed by evaporating it to dryness and igniting the residue, which will leave only magnesia and molybdic acid. It is digested with a little nitric acid to dissolve the magnesia, and then neutralised with an excess of ammonia to render soluble the molybdic acid. To the clear solution phosphate of soda is added, and the magnesia removed as ammonio-magnesian-phosphate.

To test the correctness of this mode of separating phosphoric acid, ferric oxide, alumina, lime, and magnesia, a solution was prepared, containing a mixture of these bodies in known proportions, and the following are the details of the experiments. In (a 1) and (b 1) magnesia was present, and in (a 2) and (b 2) it was absent.

As nearly all mineral phosphates contain only a few tenths of a per cent of magnesia, it would perhaps be preferable to take a fresh portion of the acid solution of the mineral, and separate the lime as oxalate, evaporate the filtrate to a small bulk, add ammonia, then acetic acid, and remove the ferric oxide and alumina as phosphates; then render the fluid alkaline, and allow to stand for some time, when the small quantity of magnesia will be deposited as ammonio-magnesian phosphate.

This plan of separating phosphoric acid, ferric oxide,

and other bases, is simple and easy, as it involves only operations of the most elementary kind, and avoids the use of sulphuretted hydrogen. It is very expeditious: the bodies may all be separated in about 12 hours,—and even this time may be shortened if the separation of the phosphoric acid, ferric oxide, and alumina, in one portion of the acid solution, and the lime and magnesia in another, are gone on with simultaneously. Although the solution from the phospho-molybdate of ammonia containing the bases is of considerable volume, it may be filtered very rapidly from the ferric oxide and alumina, and then from the oxalate of lime, if the precipitates are allowed to settle properly. The method is also highly accurate; the phosphoric acid is determined by a process which may be placed in the front rank for delicacy and correctness, and the other bodies are got with all desirable precision.

NEW RESEARCHES ON THE PHOSPHORUS BASES.*

By A. W. HOFMANN, LL.D., F.R.S.,
Professor of Chemistry in the University of Berlin.
(Concluded from page 247).

IV. Primary and Secondary Ethylic Derivatives of Phosphoretted Hydrogen.

AFTER what has been elicited by the study of the methyl compounds, there could be but little doubt as to the phenomena to be observed by repeating the experiments in the ethyl series. Nevertheless the study of the ethyl compounds presented an interest of its own. In the first place, it was desirable experimentally to generalise the new method by applying it to different groups; again the properties likely to be possessed by the ethylphosphines, and more particularly their higher boiling-points, appeared to promise that the experimental difficulties of this inquiry would be materially diminished by working in the ethyl series.

The formation of the ethylphosphines by means of ethyl iodide, phosphonium iodide, and zinc oxide proceeds with the same facility and precision as that of the methylated compounds. The digestion, however, must be conducted at a somewhat higher temperature. Exposure of the tubes to a temperature between 140° and $150^{\circ}\text{C}.$ for six or eight hours is sufficient for the transformation. The product of the reaction in this case, exactly as in the methyl series, contains the primary and secondary bases only. Their separation and preparation in a state of purity is carried out in exactly the same manner as that of the corresponding methyl compounds.

Ethylphosphine—

Colourless, transparent, mobile liquid, powerfully refractive, lighter than water, in which it is insoluble. It is easily soluble in alcohol and ether. These solutions are without any action on vegetable colours. Ethylphosphine boils constantly at 25° , and is then seen to possess exactly the boiling-point of dimethylphosphine with which it is isomeric.

The odour of this compound is overwhelming; it strongly recalls that of the formonitriles, producing more especially the same sensation of bitterness on the tongue and to the very depth of the throat. Odour and taste are, obviously, in consequence of the volatility and oxidability of the compound, far less persistent. The vapour

* A paper read before the Royal Society.

of ethylphosphine bleaches cork like chlorine; very peculiar, too, is its action on caoutchouc, which in contact with it becomes translucent, losing its elasticity. Chlorine, bromine, and nitric acid inflame the compound. Ethylphosphine combines with sulphur and carbon bisulphide, though not nearly as energetically as triethylphosphine; nor are the compounds thus produced crystalline, like the corresponding derivatives of triethylphosphine, but liquids, which are as yet but imperfectly studied.

Like the monomethylated base, ethylphosphine unites with chlor-, brom-, and iod-hydric acids to saline compounds. The solution of the chlorhydrate yields with platinum perchloride a double salt, crystallising in fine crimson-red needles, which resemble freshly-prepared crystallised chromic acid. The most beautiful salt of ethylphosphine is the iodhydrate. It forms white four-sided tables, which, in a current of hydrogen, may be sublimed even at the temperature of boiling water. The aspect of the substance forcibly recalls that of ordinary sal-ammoniac. Analysis showed that this salt possesses the composition assigned to it by theory, viz.:—

The iodhydrate easily dissolves in water, but not without being entirely decomposed. In dry air the crystals of the salt are permanent; but even when breathed upon they are altered, their decomposition being indicated by the powerful odour emanating from the crystals, which, when dry, are perfectly inodorous. When a crystal is thrown upon water, it is seen to disappear with evolution of gas. Alcohol dissolves the iodhydrate, but only with partial decomposition; in ether it is insoluble. The only solvent in which the salt was found to be soluble, though likewise but sparingly, is concentrated iodhydric acid. Addition of ether to this solution causes the salt to separate in large, well-formed tables, having often a length of 1 centimetre; they are generally so thin that their surface presents magnificent iridescence.

Diethylphosphine—

Transparent, colourless, perfectly neutral, mobile liquid, floating upon water, in which it is insoluble, powerfully refracting light. It boils constantly at 85° , i. e. 66° higher than the primary base. The odour is penetrating and most persistent, very different from that of ethylphosphine, distantly resembling that of triethylphosphine. The diethylated compound attracts oxygen with far more energy than the primary base; and more than once have I seen this compound bursting into flame on opening a bottle. Diethylphosphine combines with sulphur and carbon bisulphide; these combinations, like those of the monoethyl base, are liquids.

The secondary phosphines readily dissolve in acids. The salts, as far as my experience goes, are difficult to crystallise, with the exception of the iodhydrate. The solution of the chlorhydrate gives, with platinum perchloride, a fine platinum salt, crystallising in orange-red prisms, which are, however, easily changed. It is interesting to perceive that the salts of diethylphosphine resist the action of water, whilst those of the monoethylated base are readily decomposed; the deportment of the phosphines is thus seen to afford an instructive illustration of the increased basicity the phosphoretted molecule acquires with the number of ethyl groups it has incorporated.

Products of Oxidation of the Primary and Secondary Ethylphosphines.

It is my intention to study in detail the products of oxidation of ethyl- and diethylphosphines, which, according to special circumstances, appear to vary to a considerable extent. Hitherto I have examined only the terminal compounds. These are perfectly analogous to

the products similarly obtained from the methylated base; they need not, therefore, be more than cursorily mentioned.

Ethylphosphinic Acid.—Preparation, appearance, and properties of the body obtained by the action of nitric acid upon ethylphosphine resemble in every respect methylphosphine, and described in a previous communication. The ethyl compound is likewise exceedingly soluble in water, alcohol, and ether; it fuses at 44° , and may be distilled without decomposition. The formula $\text{C}_2\text{H}_5\text{PO}_3 = (\text{C}_2\text{H}_5)_2\text{H}_2\text{PO}_3$ was fixed by the analysis of a silver salt. This salt was formed by saturating the free acid partially with silver oxide, and precipitating the concentrated liquid by alcohol. It is an amorphous, yellowish powder, insoluble in water and alcohol, the composition of which is represented by the formula $(\text{C}_2\text{H}_{11})_2\text{H}_2\text{PO}_3$.

Diethylphosphinic Acid.—On treating diethylphosphine with nitric acid, all the phenomena present themselves which are observed in the corresponding experiment in the methyl series. The acid produced, however, has only been seen as yet in the liquid state, refusing to solidify even at a temperature of 25° . The composition of the acid, $\text{C}_4\text{H}_{11}\text{PO}_3 = (\text{C}_2\text{H}_5)_2\text{H}_2\text{PO}_3$, was established by the analysis of a silver compound. The latter was obtained by nearly neutralising the acid by silver oxide and precipitating the evaporated liquid by alcohol. The silver diethylphosphinate contains

The product of oxidation of the ethylated phosphorus bases are thus proved to be perfectly analogous to the group of methyl bodies previously described, as seen by glancing at the following table:—

Orthophosphoric acid,	$\begin{matrix} \text{HO} \\ \text{HO} \\ \text{HO} \end{matrix} \text{PO}.$
Ethylphosphinic acid,	$\begin{matrix} \text{C}_2\text{H}_5 \\ \text{HO} \\ \text{HO} \end{matrix} \text{PO}.$
Diethylphosphinic acid,	$\begin{matrix} \text{C}_2\text{H}_5 \\ \text{C}_2\text{H}_5 \\ \text{HO} \end{matrix} \text{PO}.$
Triethylphosphinic oxide,	$\begin{matrix} \text{C}_2\text{H}_5 \\ \text{C}_2\text{H}_5 \\ \text{C}_2\text{H}_5 \end{matrix} \text{PO}.$

V. Aromatic Phosphines.

The well-defined results which the easy and handy use of phosphonium iodide, as a source of phosphorus compounds, has furnished in the methyl and ethyl series, and, as I shortly intend to communicate to the Society, also in the propyl, butyl, and amyl series, very naturally created the wish of drawing the aromatic phosphines as well into the circle of my researches. It appeared especially worthy of interest to study an aniline with phosphorus in the place of nitrogen,—in other words, phenyl phosphine and, indeed, the whole series of phenylated phosphorus bases. I have instituted many experiments in the hope of obtaining these bodies, but as yet without success. Considering the remarkable inactivity of benzol chloride and analogous benzol compounds under the influence of ammonia, I could scarcely hope to form phenylphosphine by acting on phosphonium iodide with benzol chloride. Nevertheless the experiment was made; but although tried under varying conditions, I have not been able to observe the generation of phosphine bases in this process. The benzol chloride is reduced to benzol, which itself is then no further changed, even by raising the temperature, as the interesting researches of M. Baeyer have already proved.

But even the action of phosphonium iodide on phenol, from which, looking at the experience gathered in the methyl and ethyl series, I was fairly entitled to hope that at least the tertiary and quaternary compounds would emerge, gave rise to changes very different from those

anticipated. The singular phosphorus bodies generated in this reaction claim further examination. New processes, different from those hitherto followed, must therefore be devised for the production of phenylphosphine.

Exactly as in the formation of phenylphosphine, I have hitherto failed in that of phosphoretted zolucidine. On the other hand, the preparation of a phosphorus base corresponding to benzylamine presents no difficulty. Considering that benzyl chloride is easily converted into benzylamine by the action of ammonia (as the researches of Cannizzaro and Limpricht have shown), it could not possibly be doubted that by causing benzyl chloride and phosphonium iodide to meet under appropriate circumstances, an aromatic phosphorus base would be obtained.

Benzylphosphine—

For the preparation of this body it is not necessary to employ the benzylchloride in its pure state. It suffices to operate with toluol chlorinated whilst hot, which boils between 150° and 180° . The substances to react on one another are employed in the same proportions which, in the methyl and ethyl series, have yielded satisfactory results, viz., 2 mols. of benzylchloride, 2 mols. of phosphonium iodide, and 1 molecule of zinc oxide. A digestion of six hours' duration at 160° is sufficient for the formation of benzylphosphine. When the reaction is finished the digestion-tubes contain a white mass of crystals, which is generally forced out by the phosphoretted hydrogen escaping when the tubes are opened. When the product of the reaction was distilled with the vapour of water, an oily liquid, heavier than water, possessing an extremely characteristic persistent odour, passes over. This was separated from the water by means of a separating funnel, dried by allowing it to stand on caustic potassa, and submitted to fractional distillation in a current of hydrogen. It commenced boiling a few degrees above 100° ; the mercury then rose rapidly to 180° , at which temperature a large quantity of a colourless powerfully refractive liquid distilled over. That passing between 180° and 190° was collected apart from the earlier distillate, consisting chiefly of toluol (which is regenerated from the benzylchloride by the phosphonium iodide). The liquid boiling at 180° is benzylphosphine; the residue in the retort contains dibenzylphosphine and other products. Purified by a second distillation in a current of hydrogen, benzylphosphine is found to have the constant boiling-point 180° . In contact with the air the aromatic phosphorus base attracts oxygen with such avidity that the thermometer rises to 200° and more, and thick white clouds are formed.

Benzylphosphine is insoluble in water, but easily so in alcohol and ether. The aromatic phosphorus base shares the characteristic property of the other primary phosphines, viz., that of forming a crystallisable iodhydrate. This is obtained by mixing the phosphine with fuming iodic acid, when it falls as a white and apparently amorphous mass. The insolubility of the iodine compound presents an easy method of recovering any benzylphosphine that may have passed over in the first distillate containing toluol. The white precipitate of benzylphosphine iodhydrate dissolves on warming in iodic acid, and forms, as the solution cools, white needles, often more than a centimetre long, which, on contact with water, are decomposed into the acid and base. By washing with dry ether and drying in a stream of hydrogen at 100° , the iodhydrate may easily be obtained in a state of purity for analysis. In this experiment, occasionally well-formed tables are produced of considerable dimensions and great beauty. The salt has the composition—

Benzylphosphine combines likewise with concentrated chlorhydric and bromhydric acids. I have not, however, been able to obtain these compounds in crystals. The

chlorhydrate gives, with platinum chloride, a yellow insoluble precipitate.

Benzylphosphine forms, according to the equation—

This equation, however, shows only one phase of the reaction in which at the same time several other substances are formed.

Dibenzylphosphine—

This compound is contained in the liquid remaining in the retort after the distillation of benzylphosphine. By long standing, especially in presence of solid alkali, this liquid solidifies to a soft mass of crystals, which are collected on a linen filter in order to free them, by pressing, as much as possible from adhering liquid. The still strongly-coloured crystals are then dissolved in alcohol and treated with a little animal charcoal. The colourless liquid thus obtained deposits, on cooling, beautiful white crystals of the new compound. By repeated crystallisation from boiling alcohol dibenzylphosphine is obtained in a perfectly pure state. Thus prepared, the phosphine forms large brilliant needles, mostly grouped in stars or glistening tufts, perfectly tasteless and colourless, which are insoluble in water, but dissolve, though sparingly, somewhat in boiling alcohol. In ether they are nearly insoluble. The crystals melt at 205° ; at a higher temperature they volatilise, but not without partial decomposition. With the entrance of the second benzyl group, the basic characters, which in the monobenzylphosphine are still perceptible in a marked manner, have entirely disappeared. Dibenzylphosphine dissolves in no acid, nor have I succeeded in obtaining a platinum salt. In this respect the secondary aromatic phosphine essentially differs from the analogous bodies in the ethyl and methyl series, which are distinctly marked bases. This absence of basic properties cannot, however, be looked upon as strange, since even in the secondary aromatic amines the tendency to form saline compounds is very nearly effaced. The difference of dibenzylphosphine from the corresponding terms in the methyl and ethyl series becomes obvious, moreover, in its comportment with oxygen; for whilst dimethyl- and diethyl-phosphine take fire on contact with air at the ordinary temperature, oxygen is without any action even at an elevated temperature on the dibenzylated phosphorus base. As dibenzylphosphine yields no compounds, I was limited to the analysis of the body itself. This analysis led to the formula $\text{C}_{14}\text{H}_{15}\text{P}$. The formation of dibenzylphosphine ensues according to the equation—

Benzylphosphine and dibenzylphosphine are not the only phosphoretted products of the action of benzylchloride on phosphonium iodide. The mother-liquor of dibenzylphosphine contains yet another phosphorus body. The thought presented itself that it might be tribenzylphosphine; but notwithstanding many efforts, I have not succeeded in obtaining the compound in a state of purity. The mother-liquor of dibenzylphosphine consists, for the greater part, of a viscous substance, soluble in alcohol but insoluble in water, which is precipitated by lead salts. This substance tenaciously adheres to a small quantity of a crystallisable body, which most probably is no other than dibenzylphosphine. All attempts to obtain this glutinous substance (which appears to possess acid properties) in a condition fit for analysis have hitherto failed.

In conclusion I may be allowed most warmly to thank Messrs. F. Hobrecker and E. Niglius for the untiring energy with which they have—the former in the earlier stages, the latter more recently—advanced the progress of these researches.

ON A RELATION BETWEEN THE SURFACE-
TENSION OF LIQUIDS
AND THE
SUPERSATURATION OF SALINE SOLUTIONS.*

By CHARLES TOMLINSON, F.R.S., and G. VAN DER
MENSBRUGGHE.

It was stated by one of us in Part II.† that when a drop of a liquid is deposited on the surface of a supersaturated saline solution, it will do one of three things:—(1) mingle with the solution without any nuclear action; (2) spread out into a film with powerful nuclear action; or (3) assume the form of a lens, without any separation of salt. It was further stated that when a liquid forms a film or a lens, it does so according to the general proposition, that if a drop of a liquid, B, with the surface-tension b , be placed on the surface of another liquid, A, with the surface-tension a , the drop will spread into a film, if $a > b + c$ (c being the tension of the common surface of the liquids A and B); but if, on the contrary, $a = b + c$, the drop will remain in the form of a lens. Hence, if B spread on A, A will not spread on the surface of B. When the liquids A and B mingle in all proportions, c has no value. The spreading of the drop may also be interfered with by the superficial viscosity of the solution, or the greater or less difficulty in displacing the superficial molecules.

It was also stated that if a greasy smear be made upon the clean interior surface of a flask above the solution, and the flask be inclined so as to bring a portion of the solution against such smear, the liquid does one of two things:—(1) it breaks up into well-defined globules, which roll over the smear without loss of tension, in which case the smear has no nuclear action; or (2) as soon as the solution reaches the smear its edge flattens and becomes ragged, in which case the smear is nuclear and the salt separates.

A glass rod drawn through the hand becomes covered with a smear or film; or the same rod, by exposure to the air, contracts a film by the condensation of floating vapour, or a deposit of film-forming dust, and so is brought into the nuclear condition.

It was further stated that when a lens of oil is resting on the surface of a solution, the flask may be rapidly rotated or briskly shaken, so as to break up the oil-lens into a multitude of minute globules, giving the solution the appearance of an emulsion; but that by repose the solution regains much of its transparency, without any separation of salt; but that if, while the flask is being turned round, a sudden jerk be given to it, so as to flatten some of the globules against the side, the solution instantly becomes solid.

The powerful action of films in putting an end to the state of supersaturation being thus established, it occurred to one of us, who had already succeeded in explaining a number of obscure phenomena on the principle of surface-tension,‡ that that force, properly handled, would suffice to account for most, if not all, the varied phenomena of supersaturation. According to this view, whatever tends greatly to lower the surface-tension of a supersaturated saline solution, causes a separation of salt, and at once puts an end to the condition of supersaturation.

In order to test this view, a large number of experiments have been performed by one of us, during the last six months, consisting of repetitions of former experiments, or of new ones suggested by one or both of us. All these experiments have been performed in the open air at Highgate, near London, the object being to avoid all possible miscarriage from the effects of floating dust in the

air of a room. It had been suggested that some of the former results as to the action of films might have been vitiated from this source; and although this does not appear to have been the case, yet it is with much satisfaction that the experimenter refers to the greater facility and certainty with which experiments of this kind are conducted in the open air, as compared with those made in a room. In the open air a gentle wind would sometimes blow over the mouths of the flasks, sufficient to produce a low musical note, without any nuclear action, unless a speck of soot or a small insect were carried into the solution; but in general, in order to prevent evaporation, the flasks were kept covered with watch-glasses or small beakers, except when performing an experiment.

The salt used in the following experiments was sulphate of soda, in large crystals, not effloresced, one of three strengths being adopted as circumstances required, and which will be indicated when necessary, namely, 1 part of salt to 1 of water, 2 parts of salt to 1 of water, and 3 parts of salt to 1 of water. Every solution was first made in a large flask, and filtered boiling into eight or ten small flasks, which were re-boiled, covered with watch-glasses or beakers, and carried on a tray into the open air. The same experiment was repeated on a number of these solutions of the same strength.

The points to which this experimental inquiry tended are included in the four following propositions:—

- I.—That a supersaturated saline solution, contained in a catharised flask, will remain liquid so long as its free surface, or the surface in contact with the sides of the flask, does not undergo in one or many points a notable diminution of surface-tension.
- II.—That if we deposit on the surface of a supersaturated saline solution a drop of a liquid of feeble tension, it spreads, and crystallisation takes place immediately, or after a short time.
- III.—That while a liquid of feeble tension produces crystallisation after a time more or less short, a liquid of considerable contractile force (such as pure water) not acting chemically on the solution, may be brought into contact with it without producing change of state.
- IV.—That as a liquid of feeble tension produces crystallisation, so a solid covered more or less with a film of such liquid, produces change of state, either at once, or after a short time.

But before any conclusions could be drawn from the results of experiments as to the relation between the surface-tension of liquids and the state of supersaturation in saline solutions, it was necessary to measure the surface-tension of the solutions of Glauber's salt operated on. Accordingly the following data were determined, *first*, for a solution containing 1 part of salt to 1 of water, and *secondly*, for a solution containing 2 parts of salt to 1 of water. The diameter of the capillary tube was 1.598 m.m.

Specific gravity of the solution 1 salt to 1 water at 17°C. = 1.198.

The capillary height 11 m.m.

The specific gravity of the other solution = 1.289.

The capillary height 8.7 m.m.

These data give, according to the formula $t = \frac{r \cdot h \cdot d}{2}$ (in which t is the tension, h the height, d the density, and r the radius of the tube), for the superficial tensions of the solutions in question, not a greater value than from 4 to 5.2.

If the state of supersaturation of saline solutions depend on the maintenance of surface-tension, according to the first proposition, any force or substance that produces a notable diminution of such tension will cause the state of supersaturation to cease.

Such a force is heat, while such substances as camphor, benzoic acid, &c., have a marked effect in lowering the superficial tension of water, and in doing so undergo those remarkable gyrations which are so well known.

* A paper read before the Royal Society.

† *Philosophical Transactions* for 1871, p. 52.

‡ "Sur la Tension superficielle des Liquides," par G. Van der Mensbrugghe, Répétiteur à l'Université de Gand. *Mémoires couronnés par l'Acad. Royale de Belgique*, tome xxiv., 1869. See also *Phil. Mag.* for Dec., 1869, and Jan., 1870.

And first with respect to heat, applied, not so as to affect the whole solution, but locally so as to raise the temperature at one part or point of the surface, while the other parts remained at the temperature of the atmosphere.

Expt. 1.—Four flasks, each about half full of a supersaturated solution of Glauber's salt (2 salt to 1 water), were exposed to a temperature of 32° F. for an hour. A red-hot poker was then passed down the neck of each flask, and in two of them the hot metal was brought into contact with the surface of the solution so as to raise a volume of vapour. There was no separation of salt in any one case.

Expt. 2.—A solution containing a considerable mass of the seven-atom salt at the bottom of the flask was moved over the flame of a spirit-lamp in a line from the bottom of the flask to the neck, so as to heat one part only of the flask. The only effect was to convert a portion of the surface of the seven-atom salt into the anhydrous; but there was no crystallisation. After some hours the anhydrous portion had again taken up its water of crystallisation.

Expt. 3.—A solution of 2 salt to 1 water that had been in the open air during twenty-four hours was uncovered, and water nearly boiling was dropped upon it. A slight cloudiness came over the solution, but there was no crystallisation. Next day a very weak solution of Glauber's salt nearly boiling was dropped upon the surface with no nuclear action.

Expt. 4.—An eight-ounce globular flask had the globe filled with a solution of 2 salt to 1 water. Solutions of two different strengths, namely 1 salt to 1 water, and 3 salt to 1 water, at a nearly boiling temperature upon it, were dropped, but with no nuclear action.

Expt. 5.—A solution of 1 salt to 1 water had filtered into it a nearly boiling solution of 3 salt to 1 water. The drops descended to the bottom of the flask in beautiful rolling rings, but there was no nuclear action.

Expt. 6.—The neck of a flask was inclined over the flame of a spirit-lamp, so as to boil the upper part of the solution, while the lower part remained cold. Water was driven off in vapour, so as to leave a crust of salt in the neck. This, when the flask was left to itself, gradually absorbed moisture and trickled down, and was also washed down into the solution, but there was no nuclear action either from this or from the heat.

These experiments on the action of heat lead to the conclusion that, however much it may diminish the superficial tension of the solutions, it does not apparently disturb the state of supersaturation. This result may be explained with reference to the feeble tension of the solution ($=4$), and to the fact that heat locally applied does not greatly diminish it. Moreover, heat tends to oppose crystallisation by increasing the solubility.

Numerous experiments were tried as to the action of newly-sublimed camphor and benzoic acid on the solutions. The flasks containing these bodies floating on the solutions were plugged with cotton-wool and kept for some months, during which time they were repeatedly shaken, but there was no separation of salt. The camphor and benzoic acid formed weak solutions with the supersaturated solutions; but the tension of camphorated water being $=4.5$, and that of an aqueous solution of benzoic acid falling within the limits 4 and 5.2, the difference in tension is too small to produce a rupture of equilibrium. The same remark applies to a solution of soap and of bicarbonate of soda, which had no nuclear action.

Action of Vapours.—It has been shown by recent researches that the presence of vapours in the air of a room, even in minute quantity, has a marked influence in lowering the tension of water and other liquids, so as to account for the discordant values of various careful measurements of the capillary heights of such liquids. As to the nuclear action of the vapours of certain volatile liquids upon supersaturated saline solutions, many obser-

vations had been made by one of us, leading to the conclusion that such vapours are strongly nuclear when they become condensed into the form of films on the surface of the solutions, as when the latter is of a lower temperature than the former. In order to ascertain whether vapours, as such, that is, without forming films, have any nuclear action, the following experiments were contrived. The vapour was presented to the surface of the solution by means of a bit of sponge tied to the end of a glass rod, wetted with the volatile liquid and carefully passed down the neck of each flask, so as to avoid touching the side and bringing the sponge close upon the surface to avoid touching that also.* The sponge was held over the solution several minutes, then carefully withdrawn and the flasks covered, leaving the interior charged with vapour. The liquids used were ether, absolute alcohol, chloroform, bisulphide of carbon, wood-spirit, and benzole. The solutions were of all three strengths, and the temperature from 40° to 47° F. After many hours and even days the flasks had a strong odour of the vapours in question, but there was no separation of salt.

Vapour of camphor was also tried in the following manner:—

Expt. 7.—A quantity of camphor was placed in a small retort, the beak of which, made chemically clean by being heated in the flame of a spirit-lamp, was passed into a flask containing a solution of 2 parts salt to 1 of water. The camphor in the belly of the retort was then boiled so as to produce a powerful jet of vapour upon the surface of the solution. The camphor condensed upon such surface in the form of a fine white powder without any nuclear action.

In this case a portion of the vapour of camphor or of the powder would dissolve in the solution without producing in it a notable diminution of surface-tension. The same remark applies to the other vapours, to the action of solid camphor and benzoic acid, of heat, &c.

So also, as stated in Part II., glycerine mingles with the solution without any nuclear action. Now the surface-tension of glycerine $=4.2$, so that it can have no effect in lowering the surface-tension of a solution $=4$, and does not sufficiently lower the tension of a solution $=5.2$ to produce a rupture of equilibrium.

It was also stated that bisulphide of carbon $t=3.3$ to 3.5, and chloroform $=2.98$ to 3.12, formed lenses on the surface of the solution, and that on gently agitating the flask they fell to the bottom, where they remained permanently without any nuclear action. Creosote $=3$, behaves in the same manner. Now, in any one of these cases, the tension $t+c$ must be greater than 4.5, and hence there can be no separation of the salt.

(To be continued).

ON THE EMPLOYMENT OF BROMINE IN ANALYTICAL CHEMISTRY.

By P. WAAGE.

THE oxidising agents, which are principally employed to-day in chemical analysis, are nitric acid, chlorate of potassa and hydrochloric acid, and chlorine. Each of these, however, though excellent in some ways, has drawbacks to its general employment.

Among those prominent in the use of nitric acid, is the slowness with which it acts in dilute solutions; the length of time required, even when concentrated, to oxidise sulphur; that it never can be employed in platinum vessels, on account of small quantities of chlorine, which it generally contains, and that it must never come in contact

* In a few cases the wet sponge did touch the solution for an instant, so as to take up a small portion, which immediately crystallised upon the sponge; but the crystallisation thus produced, not being in contact with the solution, the latter retained its liquid state.

with organic matter, like filter-paper, if a subsequent precipitation of a metallic oxide is desired.

Chlorate of potassa acts only in the presence of somewhat concentrated hydrochloric acid, which, in larger quantities, may, under certain conditions, affect the accuracy of the work. Considerable difficulty is at the same time experienced in driving out the last traces of chlorine by boiling, especially in working with dilute solutions. Undecomposed chlorate of potassa is generally the cause of this difficulty, and addition of more hydrochloric acid will be necessary, which requires subsequent dilution before filtration.

The limit for the use of chlorine water is a narrow one, as it does not contain more than $\frac{1}{4}$ per cent of chlorine. The employment of gas is troublesome, as an apparatus must be arranged for every oxidation.

Bromine, therefore, seems to me to be the oxidising material which, being free from the drawbacks that prevent the general employment of the three above-mentioned substances, deserves a place in qualitative as well as quantitative analysis.

I employ the bromine principally in three forms,—as free bromine, as bromine-water, and as bromine in concentrated hydrochloric acid. Bromine-water, prepared by shaking an excess of bromine with water, contains between 2 and 3 per cent of bromine. Concentrated hydrochloric acid, treated in the same way, furnishes a solution containing about 13 per cent of bromine. In choosing for each case the oxidising material as to quantity and concentration, an excess may be easily avoided, and the prominent odour and colour of bromine furnish the best means to recognise an excess, which can be driven off easily by boiling, on account of the low boiling-point of bromine. Bromine-water attacks platinum neither in alkaline nor acid solutions, if the latter are free from nitric acid, and it is—in this shape or dissolved in hydrochloric acid—without action on paper, so that a metallic sulphide may be dissolved and oxidised in presence of the filter-paper by means of bromine, when the oxide can be completely precipitated by potassa or ammonia.

I have employed bromine most advantageously for the oxidation of sulphur, sulphydric acid, and metallic sulphides. For two and a half years it has been my solvent for sulphur, magnetic pyrites, copper pyrites, mispickel, nickel mattes, and precipitated sulphides, both for the determination of sulphuric acid and the metals.

Sulphur, shaken with bromine and water, is easily converted into bromohydric and sulphuric acids, if for every atom of sulphur 3 of bromine are present, or 15 by weight of bromine to 1 of sulphur. If sulphur has to be determined in this way, it is best to add all the bromine at once, so that no sulphide of bromine can be formed.

In the treatment of pyrites no necessity will exist for pulverising them very finely, as they are oxidised by bromine quite easily even in larger pieces, but it is best to add water first, and then bromine with constant stirring, that the action may not become too violent.

Bromine-water is the most convenient material for the destruction of hydrosulphuric acid. A few drops of it added to a filtrate from a metallic sulphide will immediately produce a separation of sulphur, which will as quickly be dissolved by a further addition of a few drops of bromine-water.

In dissolving precipitated metallic sulphides I proceed in the following manner:—I perforate the filter-paper, and wash as much of the precipitate as possible into a beaker. I then pour some of the bromine gas into the funnel, and cover the latter with a watch-glass, when after a few minutes the rest of the sulphide may be washed into the same beaker, and a further addition of bromine-water readily oxidises the rest of the sulphide. I thus get rid altogether of the trouble of burning the filter-paper.

Bromine liberates nitrogen in contact with ammonia, and can therefore not be employed as an oxidising agent in an ammoniacal solution. Ammonia may therefore with advantage be used to destroy an excess of bromine.

Ammoniacal salts sometimes prevent the development of the oxidising property of bromine, so that the peroxides of cobalt, nickel, and manganese cannot be formed under these conditions; iron, tin, and mercury salts will, however, be easily converted into the higher oxides in acid solutions, though they contain ammoniacal salts.

Bromine, as it usually occurs in commerce, is not pure, but contains a substance which seems to be caoutchouc, from which it must be freed by distillation in an apparatus which does not have any caoutchouc connections.—*Fresenius's Zeitschrift.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 6th, 1872.

In the absence of the President the Chair was taken by DR. GILBERT, F.R.S., Vice-President.

The minutes of the previous meeting having been read and confirmed, Messrs. J. Vincent Taylor and W. J. Wilson were formally admitted Fellows of the Society. The name of Mr. A. Liversidge was then read for the first time: for the third time—Messrs. George Elliott Barker, H. A. Smith, Richard Hayton Davies, Francis Henry de Rheims, jun., and Richard Weaver, who were then ballotted for and duly elected.

The first paper read by the Secretary was "*On a Remarkable Salt deposited from the Mother-Liquors obtained in the Manufacture of Soda*," by T. E. THORPE. This salt, which occurs in the highly-concentrated mother-liquors obtained in the manufacture of soda by Leblanc's process, has been shown by Rammelsberg to contain sodium phosphate, and by Baumgarten to contain fluorine, so that it must be regarded as a double salt analogous to fluorapatite. The crystals, which are distinctly octahedral, have a ruby-red colour, caused by some substance irregularly distributed through them: this the author believes to be phosphate of iron. By solution in water and re-crystallisation they were obtained colourless, a small quantity of sulphide and phosphate of iron being separated. An analysis showed that they have the composition $2\text{Na}_3\text{PO}_4 + \text{NaF} + 19\text{H}_2\text{O}$, and that they contain traces of vanadic acid.

"*On the Composition of Ceylon Yargons*," by M. H. COCHRAN. The author has analysed seven specimens of jargon and zircon, from different localities, adopting for this purpose the process employed by Forbes, but in no instance did he obtain indications of the presence of jargonia.

"*On a Double Sulphide of Gold and Silver*," by M. M. PATTISON MUIR. This compound, which has already been described in our pages, was obtained during some experiments made in New Zealand by Messrs. J. M. Muir and W. Carrick, with the object of separating the silver from the native alloy of gold and silver. Sulphur was passed through the molten alloy, covered with a film of borax, and was by this means raised from 654 to 812 by assay. The comparatively fusible sulphide, which has much the appearance of native sulphide of antimony, is extremely brittle, and has a specific gravity of 8.159. By heating in a current of air it remains undecomposed: hot strong sulphuric acid, however, removes all the silver, leaving metallic gold in a finely divided state. The results of the analysis correspond to the formula $2(\text{Au}_2\text{S}_3)_5(\text{Ag}_2\text{S})$.

"*On the Solvent Action of various Saline Solutions upon Lead*," by the same author. From the well-known fact that the presence of certain salts in water greatly diminishes this action on lead, and as lead is largely used for cisterns and water-pipes, the author determined to accurately investigate the effect of various saline solutions upon lead. Pieces of bright lead, having a known area, were therefore suspended in these solutions for various periods of

time, and the amount of lead dissolved estimated by Wanklyn and Chapman's colour-test. The results are given in a tabular form, from which it would appear that solutions containing nitrates, and especially ammonium nitrate, exert the greatest solvent power, whilst the carbonates have the greatest protecting power, and next to them the sulphates, so that a water containing the latter—even if a considerable amount of nitrates be present—has not a very marked solvent action on lead.

Mr. W. THORPE, in reply to a question from the Chairman, said he had not examined the action of the Loch Katrine water on lead; but as the action of waters on tarnished lead was known to be but small compared with their action on bright lead, the paper just read was merely of theoretical interest, for, practically, potable waters only came in contact with tarnished lead.

"On the Magnetic Sand of Mount Etna," by J. B. HANNAY. This sand, which exists in immense quantities on all sides of Mount Etna, has a specific gravity of 2.813, and is scarcely acted on by acids. The results of its analysis gave—Silica, 52.71; magnetic oxide of iron, 19.44; alumina, 19.09; lime, 6.61; and magnesia, 1.85.

"New Tests for some Organic Fluids," by J. A. WANKLYN. The author has found that the differential action of potassic hydrate and potassium permanganate may serve as a method to distinguish between various animal fluids. When these are evaporated down with excess of potassa solution, and then maintained for some time at 150°, a certain fixed proportion of ammonia is evolved, and if the residue be now boiled with an alkaline solution of potassium permanganate, a further definite quantity of ammonia is given off, the relative amount of ammonia evolved by these two actions being constant for the same animal fluid. The author has examined, by this method, urine, milk, blood, white of egg, and gelatine, the latter of which gives but a mere trace of ammonia by treatment with caustic potash. The quantitative results are given in a table. It would be possible by this process to distinguish between a spot of milk and one of white of egg on a cambric handkerchief.

"Dendritic Spots on Paper," by A. LIVERSIDGE. Minute dendritic marks are frequently noticed on paper, to which various observers have assigned a vegetable origin: the author, however, has distinctly proved them to be inorganic. As it was not possible to obtain a sufficient quantity for complete chemical analysis, a blowpipe examination was made, supplemented by certain special tests. The results showed that the markings consist essentially of sulphide of copper. These dendritic spots have usually a nucleus, which on examination will be found to consist of a minute particle of copper or brass, probably derived from some part of the machinery used in the manufacture of the paper. Other dendritic growths of an organic nature are occasionally found on paper, but they cannot well be mistaken for those described.

Dr. MULLER said he had long ago observed these dendritic marks, and knew them to be caused by portions of bronze detached from the paper-making machinery.

Mr. FRISWELL and Mr. SPILLER said they had both noticed similar dendritic markings on prepared albuminised paper and which were caused by the reduction of silver by metallic particles in the paper.

"On Chinoline and Leucoline," by C. GREVILLE WILLIAMS, F.R.S. M. Ballo has recently stated in a paper "On Leucoline Oil and the Pure Naphthalene of Commerce" that he obtained a copious precipitate by treating sulphate of leucoline with potassium chromate, and that by the action of amyl iodide, he obtained a violet colouring matter apparently identical with chinoline blue; but the author had always found that, although chinoline forms a crystalline salt of great beauty with chromic acid, pure leucoline gives only a yellow oily precipitate, and, moreover, by the action of amyl iodide, leucoline yields only a faint, dirty purplish colouration, having no resemblance to chinoline blue. The diversity of these results, and also those of Hofmann, would be explained

if coal-tar sometimes contained chinoline as well as leucoline. In order to settle this point, the author proposes to make comparative experiments with leucoline obtained from various sources.

A letter was then read by the secretary from Mr. Dewar, of Edinburgh, in which he mentioned that by the oxidation of chinoline he had obtained two new crystalline acids, one of which is mono-carbo-chinolic acid, $C_9H_6N.CO_2H$. Its potassium salt, when treated with lime, yields pyrrol along with the lower bases, which induces the writer to believe that chinoline is related to pyrrol and indol.

Dr. C. R. A. WRIGHT next read a paper on the "Action of Phosphoric Acid on Morphine." This action is somewhat similar to that on codeine, the polymerides being, however, at the same time, converted into "apo" derivatives by the removal of water. The mixed apo bases are immediately precipitated by sodium carbonate from the acid solution, and can in this way be separated from the unaltered morphine. This precipitate contains a small quantity of a base soluble in ether, which appears to be apomorphine, whose formula, according to the author's researches, should be $C_{68}H_{68}N_4O_8$. The portion of the precipitate insoluble in ether, when dissolved in hydrochloric acid, and fractionally precipitated, yields diapo-tetramorphine $C_{136}H_{148}N_8O_{22}$, which oxidises with great readiness. On dissolving this in strong hydrochloric acid, and evaporating, a tarry residue is obtained soluble in water. Strong hydrochloric acid precipitates from this solution the hydrochloride of a new base, $C_{136}H_{146}Cl_2N_8O_{20}.8HCl$, which differs from chloro-tetramorphine by $-H_2O_4$. Diapo-tetramorphine, when treated with hydriodic acid and phosphorus, yields the corresponding iodine compound $C_{136}H_{146}I_2N_8O_{20}.8HI$. From these results it would appear that the action of phosphoric acid on morphine is analogous to that on codeine, with the difference that the elements of water are abstracted from the products in the first case, but not in the latter. With respect to the physiological action of diapo-tetramorphine, it is quite as energetic an emetic as apomorphine.

A "Note on a Secondary Colouring Matter Produced in the Preparation of Alizarine from Anthracene" was then read by the author, W. H. PERKIN, F.R.S., in which he mentioned that he had carefully examined the secondary colouring matter mentioned in his paper on artificial alizarine formerly communicated to the Society. It is soluble difficultly in most liquids, crystallising from glacial acetic acid in minute masses of a yellow colour. Its formula $C_{14}H_8O_4$ is the same as that assigned to purpurine, but it differs from the latter in its reactions; its ethereal solution does not give the characteristic bands of purpurine, and it dissolves in alkalies with a violet colour and not a red. It also differs from alizarine in its reactions, so that it must be considered as quite distinct both from alizarine and purpurine.

"On the Effects of Temperature on the Absorption of Gases by Charcoal," by J. HUNTER, M.A. This paper contains an account of the effects of variation of temperature on the amount of ammonia and cyanogen absorbed by cocoa-nut charcoal. In the case of ammonia it would seem that the amount of the gas absorbed by the charcoal continuously decreases as the temperature rises from 0° to 55°, but at that point a sudden change occurs, and the amount of gas given off becomes considerably diminished. In the case of cyanogen the absorption takes place very rapidly, being confined almost entirely to the first ten minutes, and the curve representing the absorption between 0° and 80° is continuous. The results obtained are given in tables, and also represented by absorption curves. Hydrogen and nitrogen are very slightly absorbed by the charcoal.

Dr. ARMSTRONG then read a series of communications from the Laboratory of the London Institution: "V. On the Nitration Products of the Dibromophenol-sulphonic Acids;" "VI. On Bromophenol-sulphonic Acid;" "VII. On the Formation of Substituted Nitrophenol-sulphonic Acids." The experiments described in the first of these

papers, which have been carried out in conjunction with Mr. F. Brown, are a repetition in the bromo series of those already made by him in the chloro series, and show that the products obtained are in every respect analogous to them. Thus, by the action of nitric acid in the cold dibromophenol-sulphonic acid, $C_6H_2Br_2OH(SO_3H)$ is converted into a dibromonitrophenol, $C_6H_2Br_2NO_2OH$, melting at 132° , but undergoing decomposition at the same time; a small quantity of a nitrobromophenol-sulphonic acid, $C_6H_2BrNO_2OH(SO_3H)$ is simultaneously formed. If the heat evolved during the reaction be allowed to accumulate, however, the product consists mainly of dinitrobromophenol, $C_6H_2(NO_2)_2BrOH$. The latter body is identical with the product of the action of bromine on ordinary dinitrophenol.

In the second communication, Dr. Armstrong describes the preparation of bromophenol-disulphonic acid, $C_6H_3BrOH(SO_3H)_2$, and its conversion by nitric acid into a bromonitrophenol-sulphonic acid—

and, by the further action of the acid, into dinitrobromophenol, identical with that obtained from dinitrophenol.

In their third paper, Dr. Armstrong and Mr. F. Brown describe the action of iodine, bromine, and chlorine on an alcoholic solution of nitrophenol-sulphonic acid, $C_6H_3NO_2OH(SO_3H)$. By the action of these elements on an aqueous solution of the acid, a diiodo-, dibromo-, or dichloro-nitrophenol is invariably produced, and it does not appear to be possible to isolate any intermediate product; whereas when an alcoholic solution is employed, the reaction is found to consist in the replacement in the sulpho-acid of one of hydrogen by an equivalent of iodine, bromine, &c., giving rise to the formation of iodonitrophenol-sulphonic acid, $C_6H_2INO_2OH(SO_3H)$, &c.

The Secretary read a letter from M. E. Maumené, of Paris, thanking the Society for the interest it had testified in his theory at a previous meeting, and to Dr. E. Divers for the illustrations he had given of it. The writer then criticises the hypotheses of substitution and atomicity, "for which many chemists entertain so strange a predilection—strange indeed, for scarcely a day passes without one of them announcing that he has looked for a particular result indicated by these hypotheses, and found another;" and at the same time claims for his theory that it "gives the means of calculating true chemical actions *a priori*."

The meeting then adjourned until Thursday, June 20th, when Mr. H. Deacon has promised to give a lecture, "On Deacon's Method of Obtaining Chlorine as Illustrating some Principles of Chemical Dynamics."

CORRESPONDENCE.

QUANTITATIVE ESTIMATION OF COPPER BY MEANS OF CYANIDE OF POTASSIUM.

To the Editor of the Chemical News.

SIR,—In your journal of the 7th inst., it is stated that M. Yvon asserts that M. de Lafoillyé is not the discoverer of the cyanide of potassium process for the quantitative estimation of copper, and quotes a paper published as far back as 1859, by Buignet. It seems singular that there should be any dispute upon this point, as Mr. Parkes, in one of the numbers of the *Mining Journal* of 1851 announced the discovery, and it has been recognised in England since that time as "Parkes's Process." Some of your readers may recollect that in the first volume of the *CHEMICAL NEWS* (1860) p. 25, the writer, who had had constant practice in copper assaying, and used the salt in question, gave a full account of its application, and pointed out the metals which did and did not interfere with the desired results.—I am, &c.,

FREDERICK FIELD.

9, Belmont Park, Lee, S.E.,
June 10, 1872.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, May 13, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

Dissociation of Carbonic Acid by the Action of an Electric Current.—A. Thénard.—The author states that when a slow current of carbonic acid is passed in Houzeau's apparatus for the preparation of ozone, then that gas is decomposed into oxide of carbon and oxygen, which latter is moreover strongly ozonised.

Influence of Pressure upon the Spectrum Rays.—L. Cailliet.

Observations on the Paper of Personne on the Presence of Selenium in French-made Sulphuric Acid.—M. Lamy.

Presence of Selenium in French-made Sulphuric Acid.—A. Scheurer-Kestner.—The contents of this paper and of that preceding it mainly bear upon a question of priority of research, both authors calling attention to papers and memoirs published by them on this subject some years ago. It appears that selenium and thallium are far more frequently met with in all kinds of pyrites than is generally supposed to be the case, and the slime of sulphuric acid chambers is especially the substance wherein these two elements are to be met with.

Detection and Quantitative Estimation of the Combined Carbon in Meteoric Iron.—J. Boussingault.—The author's researches have been made with a view to ascertain whether meteoric iron contains carbon in the same condition of combination as is the case with steel and manufactured iron. For this purpose the analysis (by means of bichloride of mercury) has been made of the meteoric iron of Caille (Alpes-Maritimes, France) and of Lenarto (Hungary). The former was found to contain 0.12 per cent of combined carbon, but the latter neither contains graphite nor combined carbon.

Researches on the Action of the Opium Alkaloids, viz., Morphine, Codeine, Narceine, Thebaine, Narcotine, Papaverine, Meconine, Opianic Acid.—Dr. Bouchut.—It appears that the large number of opium alkaloids may be divided into two classes, viz., active soporific and inert alkaloids; the first-named differ greatly in their energy of action. It further appears that only morphine and codeine are active alkaloids, and the latter far less so than the former; narceine, when very pure, is a feeble soporific; but papaverine, narcotine, thebaine, meconine, and opianic acid, are—in pure state—inert substances.

Chloral Sulphhydrate (Sulphuret of Chloral).—H. Byasson.—By causing sulphuretted hydrogen to act for about 24 hours upon anhydrous chloral, there is produced a new compound,—a white solid body, emitting a very disagreeable smell, and tasting somewhat like hydrate of chloral, soluble in ether, absolute alcohol, chloroform, and crystallising from these solutions. This substance fuses at 77° and boils at 123° ; it volatilises like camphor, and its vapours blacken paper impregnated with solutions of lead salts: in contact with water the sulphuret of chloral is slowly decomposed, with deposition of sulphur, evolution of sulphuretted hydrogen, and formation of hydrochloric acid and hydrate of chloral, which remain dissolved in the water; by the action of solutions of hydrated alkalies and ammonia, sulphuret of chloral is very rapidly decomposed, chloroform being formed, and alkaline sulphurets and chloride, as well as formiate of the same base; nitric acid rapidly and very energetically decomposes the body alluded to, the result being the formation of sulphuric and trichloroacetic acids; the formula of the sulphuret of chloral is— $C_2HCl_3O_2 \cdot 2HS$.

Expansion of Moist Gases.—M. Amagat.—The following conclusions can be drawn from the author's researches:—Unless gases are thoroughly well dried, the expansion of the same is increased far less by the presence of aqueous vapour than has been supposed by some savants, who have attributed to the presence of aqueous vapour the differences which exist between the coefficients of dilatation of the different gases; that it is absolutely impossible to base a method of hygrometry (estimation of the degree of moisture in air) upon the variation of the coefficient of expansion of the air as due to moisture, since that variation is difficultly appreciable even for very great divergences of the quantity of moisture present in the air.

May 20, 1872.

In addition to several important papers and memoirs relating to geology, mineralogy, astronomy, meteorology, and natural history, this number contains the following paper relating to chemistry:—

Mineralogical Study on Grey-coloured Serpentine.—S. Meunier.—The author has examined ten different samples of serpentine,

obtained from different countries. It appears that the average composition of this rock in 100 parts is—Silica, 39.90; magnesia, 38.10; alumina, 1.25; lime, 2.0; protoxide of iron, 6.42; water, 11.60. Mineralogically grey-coloured serpentine consists of magnetite, pyroxen, peridot, and magnesite.

Bulletin de la Société Chimique de Paris, No. 1, January 1, 1872.

From the *procès-verbaux* of the meetings of this Society, we quote the following particulars:—

Preservation of Dilute Hydrocyanic Acid.—M. Petit.—The author finds that the acid diluted to one-tenth deteriorates very rapidly, while an acid diluted to one-thousandth keeps unaltered for several months; and an acid at one-tenth which already exhibits a marked alteration is preserved from further decay on being diluted to one-thousandth: it does not appear that the presence of ammonia provokes the alteration.

An Isomer of Anthraquinon.—Dr. Schutzenberger.—While repeating the experiments of Graebe and Liebermann, the author has discovered an isomer of anthraquinon, a sublimable body, crystalline, beautifully red-coloured, and much resembling alizarine, from which it is distinguished by its insolubility in potassa and ammonia: when the vapour of this substance is heated to 300° it is converted into ordinary anthraquinon.

Phosphorus and Iodoform.—M. Gautier.—When the substances alluded to react upon each other there is formed a yellowish-orange-coloured body, insoluble in almost all solvents, and yielding—when treated with boiling water—first a more bright-coloured compound, and next products of the decomposition of triiodide of phosphorus, which last-named body does not at 250° act upon chloroform.

Action of Sulphuric Acid upon Cellulose.—M. Terrell.—The cellulose is first steeped into a 1 per cent solution of iodide of potassium, and, after drying, is put into concentrated sulphuric acid, and then washed with water, whereby the cellulose becomes blue-coloured. This product does not at all resemble iodide of starch, because, when inspected by the microscope, it will be found to consist of red- and of blue-coloured globules.

This number further contains the following original memoirs and papers:—

Method of Separation of Two Isomeric Toluidines.—Dr. Rosenstiehl.—This lengthy essay is divided into the following sections:—Analytic separation; estimation of toluidine; preparation of pseudotoluidine; method of supersaturation; method based upon the different solubility of the oxalates in water; method based upon fractionated saturation.

Chemical Research on the Crystalline Substance met with on Vanilla.—P. Carles.—After briefly referring to the researches made by other scientific chemists on this substance, and pointing out that the great discrepancies of the results lead to the surmise that the same substance has not always been investigated, the author states that he operated upon the crystals which are usually deposited in the tin canisters in which vanilla is kept. The purified material is an acid termed vanillic acid; it fuses at about 81°, sublimable when heated on platinum foil, very readily soluble in alcohol, ether, chloroform, sulphide of carbon, and in fixed and volatile oils; water at 15° dissolves only 1/2 per cent of this acid, but in boiling water it is readily soluble; mineral acids decompose it, and it yields substitution products with chlorine, bromine, and iodine; vanillic acid colours salts of iron blue, reduces nitrate of silver, and yields an abundant precipitate with acetate of lead. The formula of this acid is $C_{10}H_8O_6$. The author describes, at great length, a number of its salts and some of its substitution products; by fusion with caustic potassa, it yields oxyvanillic acid, $C_{10}H_8O_6$; it is isomeric with anisic, formobenzoic, methylsalicylic, and a series of other acids.

Production of Cymen by means of the Hydrate of the Oil (Essence) of Turpentine.—P. Barbier.—The hydrate of the oil of turpentine (terpine), $C_{10}H_{16}O$, has been treated with bromine, yielding a thickish liquid—an unstable compound—which, on being acted upon by caustic potassa, is found to consist of a dibromated and tribromated compound, both free from oxygen: by heating these substances cymen is obtained, in all respects akin to the cymen of camphor, viz., a colourless, very fluid liquid, of a lemon-like odour, sp. gr. at 15° = 0.864.

No. 2, January 15, 1872.

This number does not contain any original papers or memoirs.

No. 3, February 1, 1872.

New Isopropyllic Ethers.—M. Silva.—The formate is obtained by heating iodide of isopropyl with formiate of copper to 120°: this ether boils at from 65° to 67° under pressure (barometer reading) of 749 m.m. The lactate of mono-isopropyllic ether has been prepared by heating—in a sealed tube—to 170°. Lactic acid and isopropyllic alcohol:—this ether is soluble in water, and boils at from 166° to 168°; the di-isopropyllic lactate is obtained from the former by treatment first with sodium, and next with iodide of isopropyl. The resulting ether is soluble in water, and has a very high boiling-point; the cyanate of isopropyl is a liquid which boils at 74.5°, and has a vapour density of 2.943.

This number further contains the following original papers:—

Ammoniacal Platinum Bases.—P. F. Clève.—The third instalment of a lengthy monograph on this subject, divided into the following sections:—Platinamine—

bromide, iodide, basic nitrate, nitrated nitrate (*oxalate nitri*), nitrated and chlorated nitrate, bichlorated nitrite, bichlorated nitrite and nitrite of silver, perchlorated nitrite, bromated nitrite, sulphate, basic sulphate, oxalate, and hydrate, of this base. Platino-semidiamine—

chloride, polyiodide, nitrate, chlorated nitrite, bromated nitrite, basic monochlorated nitrite, sulphate, of this base. Platinum monodiamine—

chloride, nitrate, bromated nitrate, basic monobromated nitrate, bromated sulphate, of this base. Diplato-semidiamine—

hydrate, chloride, nitrate, sulphate, of this base.

Volumetrical Estimation of Zinc.—A. Hénninger.—The author describes a process of estimating zinc by means of sulphide of sodium, the zinc being in ammoniacal solution. In order to test for the presence of a slight excess of the sulphide, the author recommends, as the most sensitive substance, that kind of so-called enamelled *carte-de-visite* paper which owes its brilliant whiteness to carbonate of lead (white-lead) forced into the pores of the paper by hot-pressing: it is clear that, when operating on zinc ores, the other metals accompanying the zinc have first to be removed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 8, 1872.

This number contains the following original papers and memoirs:—

Solubility of Sugar in Mixtures of Water and Alcohol, at Different Degrees of Concentration and at Varying Temperatures.—C. Scheibler.—This excellent monograph, elucidated by a series of lengthy tabulated forms, and by a lithographic print exhibiting results of experiments, is not well suited for any useful abstraction.

Action of Permanganate of Potassa upon Tartaric Acid.—A. Fleischer.—After first referring to the researches of Péan de St. Gilles on this subject, the author describes the results of a series of experiments made with and without the addition of a mineral acid to the tartaric acid solution to which a permanganate solution is added. It was found that, when no mineral acid is added, there is formed a certain amount of a tartrate of protoxide of manganese—

This salt is soluble in tartaric and mineral acids, insoluble in alcohol, oxalic acid solution, treated in a similar manner with permanganate, yields oxalate of protoxide of manganese; citric acid, when treated with permanganate solution only, is also partly decomposed, but no salt akin to those just alluded to is formed.

Communications from the Chemical Laboratory of the University at Freiburg, in Breisgau (Baden).—A. Claus.—This paper is divided into the following sections, the contents of which, notwithstanding their high scientific value, are not well suited for any useful abstraction:—On dichlorhydrin; on dichlorglycid; on carbathalidin; on the preparation of azobenzol; on azophenylene, a new nitrogen compound belonging to the aromatic series.

On Nitro-naphthalins.—A. A. de Aguiar.—This essay, illustrated by woodcuts exhibiting crystallographical figures, treats at length on the nitro-compounds of naphthalin, viz., mononitro-naphthalin, best prepared by dissolving the naphthalin in very highly concentrated glacial acetic acid, and treating this solution with strong nitric acid, ebullition being resorted to for a few moments; it depends upon the degree of concentration of the nitric acid, and upon the duration of time of its action upon the naphthalin solution, what nitro-compound will be formed; the mononitro-naphthalin is a sulphur-yellow-coloured, prismatically-crystallised body, soluble in alcohol, better still in glacial acetic acid, fusing at 61°, formula $C_{10}H_7(NO_2)$; of dinitro-naphthalin, an α and β compound are distinguished, the formula of each is the same, viz., α and β $C_{10}H_6(NO_2)_2$,—a dinitro-naphthalin fuses at 216°, the β compound at 170°; of trinitro-naphthalin, also an α and β compound are distinguished, formula α and β $C_{10}H_5(NO_2)_3$,—the α compound fuses at 122°, the β at 218°; of tetranitro-naphthalin, likewise an α and β compound are distinguished, the formula for these being— α and β $C_{10}H_4(NO_2)_4$,—the α body melts at 259°, the β at 200°.

Synthesis of Carbazol.—C. Graebe.—After first referring to the communication made by Braun and Greiff (*CHEMICAL NEWS*, vol. xxv., p. 191), the author states that he obtained carbazol from aniline, by slowly passing that fluid through a very highly-ignited porcelain tube; there are formed by this operation large quantities of hydrogen and ammonia, while cyanide of ammonium is also produced. Carbazol is in this instance produced according to the following formula:— $2C_6H_5N = C_{12}H_9N + H_2 + NH_3$. The author states that carbazol is to be viewed as imidodiphenyl, formula—

diphenylamin, when passed through a red-hot tube, also yields carbazol.

Preliminary Communications.—I. Remsen.—The author states that (1) by the reaction of V. Meyer (not further explained), parasulphobenzoic acid is converted into perfectly pure terephthalic acid; (2), when paratoluol sulphamide is oxidised with bichromate of potassa and

sulphuric acid, it is converted into an acid, which contains the group SO_2NH_2 ; this new acid is parasulphamin benzoic acid—

Products of Iodisation (Iodirung) of the Isomeric Acids $\text{C}_7\text{H}_5\text{O}_3$.—MM. Hlasiwetz and Weselsky.—After first referring to some researches made by the authors some three years ago, relating to the substitution of the hydrogen of phenol by iodine, the authors now state that they have tried this process with great success on the three isomers of the formula $\text{C}_7\text{H}_5\text{O}_3$, whereby it was found, however, that in some cases all—in others only a portion—of the hydrogen was eliminated, this difference being due to the different position occupied by the hydrogen atoms in the organic molecule.

Contribution to the History of the Isocyanuric Acid.—A. Steiner.—Notwithstanding its high scientific value, the contents of this essay are not well suited for any useful abstraction, an observation which also applies to the following memoir.

Determination of the Constitution of Alcohol Radicals by the Oxidation of Aromatic Hydrocarbons.—A. Popoff and T. Zincke.

No. 9, 1872.

This number contains the following original papers and memoirs:—

Nitro-Compounds of the Fatty Series.—V. Meyer and O. Stüber.—The first instalment of a monograph on this subject. This portion is divided into the following sections:—On nitro-ethan; action of iodide of ethyl upon nitrate of silver; action of iron and acetic acid upon nitro-ethan; action of alkalis on nitro-ethan.

Application of Sulphuretted Hydrogen as a Reagent in Researches and Tests made on the Dry Way.—J. Landauer.—The author describes at some length the results of some experiments which led to the discovery that, when a metallic compound is mixed with some pulverised hyposulphite of soda, and then heated upon a bead of borax in the inner blowpipe-flame, then the peculiarly characteristic reactions sulphuretted hydrogen exhibits with metallic solutions are readily brought out. This paper is illustrated with a diagram exhibiting the names of a large number of metallic oxides, their behaviour with $\text{Na}_2\text{S}_2\text{O}_3$ and with a borax bead alone in the oxidising and reduction flames.

Preliminary Observation on the Ready Evolution (Abspaltung) of Hydrocyanic Acid from Nitro- and Dinitro-Benzol and Similar Compounds.—J. Post and H. Hübner.—The authors, after alluding to an observation made as far back as the year 1828 by Dr. Wöhler (*Pogg. Ann.*, xiii., 488), viz., that picric acid yields, by treatment with baryta water, hydrocyanic acid, state that they recently found that even dinitrobenzol, when boiled with caustic soda or potassa solution, becomes decomposed, hydrocyanic acid being evolved, which the authors converted into cyanide of silver and ferro-cyanide of iron (*alias* prussian blue). The dinitrobenzol operated upon was perfectly pure; the alkali was prepared from sodium, and, as regards potassa, specially tested for its perfect purity. Mononitrobenzol yields hydrocyanic acid when fused with caustic alkali, and picric acid does the same when boiled with a solution of that substance.

Pentahydrated Sodium Metasilicate, $\text{Na}_2\text{O} \cdot \text{SiO}_2 + 5\text{H}_2\text{O}$.—T. Petersen.—While visiting a chemical factory, the author obtained from the manager a crystalline substance which had been separated from the mother-liquor of a crude caustic soda lye. The crystals are large-sized, colourless, transparent at first, but become turbid by exposure to air; they fuse readily in their water of crystallisation. After ignition a white bulky mass is left, which is readily soluble again in water. This substance consists, in 100 parts, of—Silica, 28.30; soda, 29.25; water, 42.45. To this paper is added a crystallographical description, illustrated with woodcuts.

Estimation of Uric Acid.—E. Salkowski.—This paper contains a rectification of Schwanert's assertion that the author's (Salkowski) researches on this subject are incorrect, the last-named author pointing out that Schwanert has not read his more extensive memoir published on this subject.

Some Molecular Combinations of Phosphorus-Bromochloride and Bromine.—A. Michaelis.—Notwithstanding the high intrinsic merits of this lengthy memoir, its contents are not well suited for useful abstraction.

Sulpho-Acids of Aniline Blue.—C. Bulk.—This exhaustive monograph is divided into the following sections:—Triphenyl-rosaniline-monosulpho acid, $\text{C}_{20}\text{H}_{16}(\text{C}_6\text{H}_4)_3(\text{SO}_3\text{H})\text{N}_3 + \text{H}_2\text{O}$; triphenyl-rosaniline-disulpho acid; triphenyl-rosaniline-trisulpho acid; triphenyl-rosaniline-tetrasulpho acid; sulpho acids of aniline violet; sulpho acids of ethyl-phenyl-rosaniline.

Researches on the Constitution of the Benzol-Derivatives.—V. von Richter.—The third instalment of an exhaustive memoir on this subject. The author deduces the following classification of the benzol-derivatives from his researches:—

Chinon.	Dinitrobenzol.	Volatile nitrophenol.
Oxybenzoic acid.	Salicylic acid.	Paraoxybenzoic acid.
Phthalic acid	Isophthalic acid.	Terephthalic acid.
(1,2)	(1,3)	(1,4)

Composition of Two Varieties of Crystallised Cast-Iron.—Dr. C. Kammelsberg.—In one of the samples the iron alluded to was derived from a broken rail-rolling cylinder at the Henrichs Works, near Hattingen-on-the-Ruhr (Rhenish Prussia). This iron was crystalline, exhibiting regular octahedral crystals, sp. gr., 7.285. Electro-negative compounds present in the following quantities, per cent:—

Graphite, 1.22; carbon, 1.963; silicon, 1.337; sulphur, 0.113; phosphorus, 0.041. The atomistic relation of these elements to that of the iron is as 1 : 7.6. Sample of iron from the Friesenbruch Works (Nova Scotia), metal also crystalline, sp. gr. 7.617:—Quantity of graphite, a trace; quantity of the following elements, per cent—carbon, 2.820; silicon, 0.334; phosphorus, 0.086; sulphur, 0.000; C, Si, P : Fe = 1 : 7 and P : Si : C = 1 : 4.3 : 84; Si : C = 1 : 19.5.

La Revue Scientifique de la France et de l'Etranger,
May 18, 1872.

This number contains a very exhaustive review of Dr. Berthelot's recently published work:—

Organic Chemistry.—E. Alglave.—This extensive memoir is too concisely written to admit of any useful abstraction, but it appears that the work alluded to, "Traité de Élémentaire de Chimie Organique," is in every respect a standard work that deserves the attention of all scientific chemists.

May 25, 1872.

This number does not contain any original papers relating to chemistry.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
April 4, 1872.

Description of a Newly-devised Arrangement of Retorts for the Distillation of Bituminous Shales.—M. De Jussieu.—From what is here stated it appears that the arrangement described effects a considerable saving of fuel for heating, while, moreover, the retorts do not require renewal for a very long period of time.

Pulverised Bricks in Lieu of Hydraulic Cement.—C. Mène.—The author states that in Cuba, and other Spanish colonies, there is used, in lieu of hydraulic cement, a mixture, consisting of 1 part of pulverised bricks, 1 part of lime, and 2 parts of sand. These ingredients are well blended together in a dry state, and then made up as mortar is, with water.

Description of a Contrivance for Hermetically Closing Doors so as to prevent Draughts of Air.—M. Chailiès.—This description is illustrated by a series of woodcuts. It appears that this contrivance is used with great success in Paris, to prevent draughts of cold air entering rooms, houses, workshops, &c., through the chinks of the doors.

MEETINGS FOR THE WEEK.

MONDAY, June 17th.—Anthropological, 8.

TUESDAY, 18th.—Zoological, 9.

WEDNESDAY, 19th.—Meteorological, 7. (Anniversary).

Geological, 8.

THURSDAY, 20th.—Royal, 8.30.

Royal Society Club, 6.

Zoological, 4.

Chemical, 8. Mr. H. Deacon, "On Deacon's Method of obtaining Chlorine as Illustrating some Principles of Chemical Dynamics."

TO CORRESPONDENTS.

* * Vol. XXIV. of the CHEMICAL NEWS, containing a copious index, is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 3s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxv. commenced on January 5th, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each, post free, may also be obtained at the Office.

A. P. S.—Consult work by Dr. Dufois. See "Notes and Queries" column, vol. xxiv., p. 313. See also "Reviews of Works," by same author, vol. xxiii., pp. 81 and 224.

G. P.—Reimann's "Aniline and its Derivatives," edited by W. Crookes, F.R.S., was published some time since by Longmans. Another work on Dyeing will appear in the autumn.

J. M.—The paraffin received was not good. Get a specimen from a respectable operative chemist.

F. M. R.—Papers by Mr. Stanford and others have frequently appeared in our columns. Consult the Index.

E. W. Prevost.—The No. was sent from our office.

Robinson Bros.—Wrote to Hachette and Co., 180, King William Street, Strand.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of Six dollars or £1 2s. 4d. per annum payable in advance.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE and Co., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of **PRACTICAL CHEMISTRY**, particularly in its application to **MEDICINE, AGRICULTURE, and COMMERCE.**

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake **ANALYSES** of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

AMSTERDAM EXHIBITION, 1869.

The **GRAND DIPLOMA of HONOUR**, being the First Prize, and **SUPERIOR** to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by **BARON LIEBIG**, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require **BARON LIEBIG's** signature upon every jar. Sold by all Italian Warehousemen, Grocers, Chemists, and Ships' Store Dealers; all Wholesale Houses; and of **LIEBIG'S EXTRACT of MEAT COMPANY (LIMITED)**, 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with *boiling-hot* water will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British French, Prussian, Russian and other Governments.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also **FINISH, FUSEL OIL, and RECT. NAPHTHA.**

Silicates of Soda and Potash in the state of

Soluble glass, or in **CONCENTRATED SOLUTION** of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by **W. GOSSAGE and Sons**, Widnes Soapery, Warrington.

London Agents, **CLARKE and COSTE**, 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

ESTABLISHED 1798.

ROBERT DAGLISH & CO., BOILER MAKERS, ENGINEERS, AND MILL-WRIGHTS, BRASS AND IRONFOUNDERS, ST. HELEN'S FOUNDRY, LANCASHIRE.

Makers of every description of Chemical, Colliery, Copper Ore Mining, and Glass Machinery, including Crown, German Sheet, and Plate Glass Plant, as supplied to some of the largest Firms in England, Ireland, Scotland, and Wales.

Makers of the latest Improved Revolving Black Ash Furnace, with Siemens's Patent Gas Arrangement, and as used in the Manufacture of Soda.

Improved Vertical Blowing Engines (which have given a much higher Blast than any others have yet obtained), and as supplied to the entire satisfaction of most of the largest Bleaching Powder Manufacturers who have adopted "Weldon's Patent Process."

Authorised by Patentee to supply the Ironwork and Plant required in the Manufacture of Bleaching Powder by "Deacon's Patent."

Plans and Estimates of the Plant required for working these Patents in accordance with the Patentee's instructions.

Photographs, Prices, and other information, supplied on receipt of Order.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at **ROBERT RUMNEY'S**, Ardwick Chemical Works, Manchester.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under $\frac{1}{2}$ per cent.

CHLORIDE of BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{2}$ per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

W. NEILL & SON'S PATENT BLOWING ENGINES, ACID PUMPS, AND DONKEY PUMPS, ESPECIALLY ADAPTED FOR WELDON'S PATENT CHLORINE PROCESS.

W. NEILL and SON have just Patented most important improvements in the Air-Valves of Blowing-Engines, which enable them to secure the most perfect "Cut-off" at the termination of each stroke, together with a perfectly free inlet and outlet for the Air at the proper time, thus securing a much better result from each stroke of the Air-Piston, with greater freedom of action, also a very great saving in the wear and tear of valves.

These improvements are of especial advantage to Engines working under the comparatively high pressure of blast required in the Weldon Process.

W. Neill and Son have supplied Blowing Engines and Pumps to all the principal Alkali Makers who have adopted the Weldon Process, and are ready to furnish Plans and Estimates for the erection (with the latest improvements) of the whole of the Plant required.

Efficiency and Simplicity of Construction, with the best workmanship, guaranteed. References on application.

W. NEILL and SON, ENGINEERS, &c.,
BOLD, ST. HELEN'S JUNCTION, LANCASHIRE.

OXIDE OF IRON.

We are prepared to supply, on moderate terms, **HYDRATED PEROXIDE OF IRON (BOG OCHRE)**, Same quality as supplied by us to several of the most extensive Gas Companies, and which has given entire satisfaction.

FRANCIS RITCHIE AND SONS, BELFAST.

PATENTS.

MR. VAUGHAN, F.C.S., Memb. Soc. Arts, British, Foreign, and Colonial PATENT AGENT, 54, Chancery Lane, W.C., gives special attention to Inventions connected with Chemistry, Metallurgy, and Mining.

A "Guide to Inventors" Free by Post.

THE CHEMICAL NEWS.

VOL. XXV. No. 656.

THE FARADAY LECTURE,

DELIVERED BY

PROFESSOR CANNIZZARO

BEFORE THE

MEMBERS OF THE CHEMICAL SOCIETY OF LONDON,

MAY 30, 1872.*

THE meeting was held in the Lecture Theatre of the Royal Institution, kindly lent for that purpose; DR. FRANKLAND, F.R.S., the President of the Society, occupying the Chair.

Dr. FRANKLAND, in introducing Professor CANNIZZARO, explained that the lectureship had been founded by the Chemical Society in honour of the illustrious Faraday, to be held by some eminent foreign *savant*, who, during the term of his tenure, was to deliver a discourse before the Society. In 1869 M. Dumas had honoured them with his presence there, and on that night they were to listen to Professor Cannizzaro, of Palermo, who had undertaken to deliver the Faraday lecture. After alluding to the numerous investigations which the Professor had made in organic chemistry, and amongst others the discovery of benzylic alcohol,—the first normal aromatic alcohol that had ever been prepared,—and to the important theoretical views which he had originated, the President, in the name of the Society, presented to him the Faraday medal struck in honour of his visit.

Professor CANNIZZARO said, that when he received the flattering invitation to deliver the Faraday lecture he was placed in very unfavourable circumstances to respond to it, as he had no definite results from recent researches to lay before the Society, and was, moreover, on the point of suspending his labours, and abandoning his old laboratory, in order to remove to Rome and establish a new one there. In this difficulty a subject for a discourse fortunately presented itself, and which the celebrated French chemist Dumas, had promised to treat of in 1847,—namely, the form which the theory of chemistry should take at the present time. Although this could not be fully discussed in such a short space of time, it would at least have the advantage of directing the attention of chemists to a question of great importance in the transition stage which our science is at present going through.

In recalling the promise which M. Dumas had made to the Academy of Sciences of Paris, in 1847, to examine the form which theoretical instruction in chemistry should take in the present state of the science, the lecturer proposed to consider in his discourse the limits within which the exposition of general theories should be included in teaching chemistry, and the form that it was desirable that it should assume.

Whilst giving a broad sketch of the progress of modern chemistry, he showed that the atomic theory had become more and more intimately interlaced with the fabric of chemistry, so that it is no longer possible to separate them without rending the tissue, as it were, of the science, and that up to the present time we have been unable to enunciate even the empirical laws of chemical proportion independently of that theory; for those who employ the term "equivalent" in the sense that Wollaston did, commit an anachronism. Consequently, in the exposition of the value and use of symbols, formulæ, and chemical equations, not only are we unable to do without the atomic and molecular theory, but it is even inconvenient to follow the long and fatiguing

path of induction which leads up to it. By one of those bold flights of the human mind we can at once reach the height whence we discern, at a glance, the relations between facts.

He then went on to show that the solid basis, the corner-stone of the modern molecular and atomic theory,—the crown of the edifice of which Dalton laid the foundation,—is the theory of Avogadro and Ampère, Koenig and Clausius, on the constitution of perfect gases, to which chemists, unknown to themselves, have been led in the progress of their science. He thought the time had arrived for reversing the order which had hitherto been followed in teaching chemistry; that instead of setting out from the criteria for determining the weight of the molecules, and then to show their ratio to the vapour densities, they ought, on the contrary, to commence with the latter, with the theory of Avogadro and Clausius, demonstrating it from physical considerations; to found upon that the proof of the divisibility of simple bodies, that is to say, the existence of atoms; and to show, as occasion presented itself, that the weights of the molecules, and the numbers of the atoms deduced by the application of this theory, are in accordance with those which are deduced from chemical criteria. By this means we can measure the degree of confidence to be placed in the latter criteria, since so-called compound equivalents do not suffice to determine the weight of molecules, or even to prove their existence. They may, however, be deduced from a single principle—the theory of the constitution of gases: this is the natural transition from physics to chemistry.

The Professor then stated, in detail, how he applied the principles he had laid before them. He introduced his pupils to the study of chemistry, in endeavouring to place them on the same level as the contemporaries of Lavoisier, and to teach them to appreciate the importance of the principle of the conservation of the weight of matter, showing them that this is quite independent of any idea of its nature or constitution. They are thus led to examine the ponderable composition of substances, so that the student passes rapidly from the epoch of Lavoisier to that of Proust, and then to that of Berzelius at the time when he commenced his researches on proportions. At this stage the same impulse is given to the pupil as Berzelius received on becoming acquainted with the hypothesis of Dalton. The latter is laid before him without any accessory, the use of symbols and formulæ being introduced dogmatically. There will now arise in his mind the same doubts and difficulties that assailed Berthollet, Sir Humphrey Davy, and Wollaston, in the application of Dalton's theory, and, at the same time, a desire for an explanation of the simple relation which exists between the vapour-volumes of bodies which react on one another, and of the products which are obtained. Now is the moment to state or recall to mind the physical theory on the constitution of the perfect gases, commencing with a rapid glance at their general and special characters. He insisted that in this part of the instruction the mind of the student should not be diverted from the numbers expressing their relations, by any considerations of the variations caused by changes of temperature and pressure. In applying the theory of the constitution of gases, it will be perceived that the molecules of simple bodies are not always the atoms of Dalton, and a certain confusion will thus be produced in the mind of the beginner in the conception of the ideas of atoms and molecules. The hypothesis of Dalton can now be laid aside, substituting, as a starting-point, the theory of the relation of molecular weights to the vapour densities. A table must be prepared of the vapour densities compared with that of hydrogen as 2, that is to say, the weights of their molecules compared with the weight of the semi-molecule of hydrogen taken as unity. We must then compare the composition of the molecules containing the same element,—including, or not, the molecule of the element itself,—and thence deduce the law of the existence

of atoms, that is to say, the amount of each element which always enters, by whole multiples, into the molecules which contain them. We here have the atoms of Dalton, which, in the present state of the science, express not only all that Dalton discovered, but also the composition of equal volumes of their vapours, and in the choice of which those doubts can no longer arise which embarrassed Davy and Wollaston. The ideas of molecules and atoms suggested to the student by this law are devoid of all considerations of form, size, continuity, or discontinuity; the only property indissolubly connected with them is that of ponderability—the very definition of matter.

Recollecting that no physical theory of the constitution of matter had yet been advanced which thoroughly conformed to chemical ideas, he insisted upon the advisability, in teaching the molecular and atomic theory, to keep it free from all that is not absolutely essential, so that it may preserve sufficient plasticity to adapt itself to the progress of our physical and mathematical knowledge. For this purpose he thought it useful to allow the student, in the first place, to glance at the changes in the hypothesis of the constitution of matter, and then to cause him to estimate the degree of confidence it merits in the actual state of our knowledge. Having thus placed upon a solid basis the fundamental notions of atoms and molecules, by the comparison of the composition of equal volumes of the bodies in the gaseous state, it becomes necessary to consider the difficulties which arise in the application of these notions when the vapour densities are wanting: he explained and justified the use of the various auxiliary criteria to which we have recourse in these cases, proving them, in the first instance, by the touchstone of the theory of Avogadro and Clausius, by showing that they gave results in accordance with that theory whenever the two methods can be employed simultaneously.

He believed that we should never lose sight of the starting-point, nor give the formulæ of all compounds as of equal probability. "It is not by concealing the obscurity of these questions that we shall enlighten the student; on the contrary, we should estimate each fact at its true value, by showing him that our science does not merit an equal degree of confidence on all points." This forms the introduction, the preparation for the study of the transformations which matter undergoes—the real object and aim of our science.

The comparison of the atomic composition of molecules has led chemists to the law of substitution, to the theory of types of Dumas, then to that of Williamson and Gerhardt, and, lastly, to the theory of the different valency of atoms and their modes of union, or the so-called theory of atomicity which includes the former. Although at present it is impossible, in teaching chemistry, entirely to eliminate this latter theory, which gives a summary of several laws, and guides us ordinarily in the co-ordination—and even prevision—of a large number of facts, yet it is difficult to keep it within just bounds, so as to avoid infusing into the mind of the beginner illusions which are dangerous for their intellectual education. In order to avoid this, it is advisable to bear in mind the progress of this doctrine, and the actual phase of development which it has at present reached. It is still far from being a complete and well-established theory, but is in a state of transition, for although, doubtless, it embraces a large number of facts, as yet it does not embrace them all. It is only a partial representation of the reality, and that from a restricted point of view, showing but little relation to our views of the constitution of matter, for it is the result of a comparison of diverse facts expressed by means of the atomic and molecular theory. It is convenient, therefore, to consider each part of this doctrine exclusively in relation to the group of facts which has suggested it.

It is unadvisable to define the valency of atoms as a property inherent in them, and then to deduce as a corol-

lary their different modes of union; on the contrary, it is preferable to regard each portion of this doctrine as a deduction from the observation and comparison of a determinate group of facts, until an opportunity offers to unite these fragments into one whole, not forgetting, however, to notice the gaps which exist,—never going beyond what the facts themselves suggest, and never applying to all bodies indiscriminately the laws which suit only a single group. For instance, we must not pass over in silence the fact, that whilst certain elements are bi-, tetra-, or even hexa-valent, others are tri- and penta-valent; but the pupil should be prevented from acquiring mechanical and geometrical ideas of the cause and effects of the valency of atoms, by frequently reminding him that chemical facts show nothing about the size, form, continuity, or relative position of atoms. If we are sometimes obliged to employ the expression, "relative position of atoms in the molecules," and even to represent them graphically, we must warn the student that these are only artifices to express certain transformations, and that we are really ignorant of the relative position of the atoms, either in space or in the mutual action of different portions of matter. With these reservations it is possible, in teaching, to derive considerable advantage from the theory of atomicity, and at the same time avoid its inconveniences.

In the study of the transformations which matter undergoes, we should direct the pupil's attention not only to the ponderable changes in the composition of molecules, but also to the electrical and calorific phenomena which accompany these transformations. Even from Lavoisier's time, it has been recognised that we cannot separate the study of matter from thermic considerations, and every day the connection which exists between chemical and thermic phenomena becomes more apparent.

As in the study of ponderable changes we were guided by the law of the conservation of weight, so in the connection between chemical and dynamical phenomena, we are guided by the law of the conservation of force, the two studies mutually supplementing and illustrating one another. Not only will the atomic and molecular theory and that of atomicity help us to compare dynamical phenomena, but the study of dynamical phenomena will show us analogies and differences between chemical actions which would not be observed in the ponderable equations. We should, therefore, instruct the student in the little definite knowledge which we at present possess concerning thermic and electric phenomena, and especially fix in his mind the fundamental notion of a mechanical equivalent, and the manner of comparing it with chemical action as expressed by the atomic theory. In this we should be aided by the previous or simultaneous instruction of the student in physics under the form and language of the thermo-dynamic theory.

The lecturer concluded by observing that in the choice of methods and of matter for a course of chemistry, it should always be borne in mind that it was eminently a progressive science, and that, even at the time of its most rapid development. The student should start not only with a knowledge of certain definite and fixed principles, but with an aptitude, and sufficient preparation to enable him to follow the science in its unceasing transformation and progress, whether he intends to expressly cultivate chemistry, or has only learnt the elements of the science as an auxiliary to other studies or professions. Moreover, the end of chemical instruction for both these classes of students is not only to fix in their memory a certain amount of knowledge, but to assist in their intellectual education. For this, chemistry, of all sciences, is one of the best, offering, both in verbal and practical instruction, excellent occasions for the exercise and harmonious development of all the faculties of the human mind.

He had desired to call attention to what he considered to be the most efficient means of imparting a knowledge of chemistry, so that it might serve as an instrument of

Intellectual education, and that the student, by following it in its ulterior developments, might judiciously apply it to the study of the other branches of natural science. If the attention of the eminent chemists and professors there present were once attracted to this subject, he felt certain that a bright light would be thrown on it, and that our young professors would find numerous suggestions to direct them in teaching chemistry, and that at the very moment when instruction in our science had become so difficult on account of the rapid transformation which it was undergoing.

Dr. WILLIAMSON said that those who were present ought not to separate without some expression of the pleasure that they had felt in listening to so learned, vast, and eloquent a discourse, treating as it did of a most difficult and important problem. There was scarcely anything of greater moment in the scientific education of youth than the rightly setting before them those wonderful transformations of matter which it is the province of chemistry to explain. These great and growing truths,—for, as the lecturer had said, they were growing truths,—should be set before youth in such a manner as to form a coherent whole. He hoped to study this masterly discourse with profit and delight, and would now propose a vote of thanks to his illustrious colleague for the honour which he had done them in delivering to them the Faraday lecture.

Professor TYNDALL said he had heard the discourse with deep interest, for it showed that the lecturer knew the importance of a teacher's vocation, and that his province was not merely to communicate knowledge, but to do it in such a manner as to arouse an interest in, and love of, the subject in the pupil by preserving it in its proper relations. He would have welcomed the lecturer to that Institution even had he come to tear in pieces the notions which he cherished regarding atoms and molecules; how pleasant it was, then, to find such a broad agreement between their views. The chemist cannot halt at equivalent proportions: he *must* ask himself whence they arise, and the inevitable answer is some form of the atomic theory. This theory, however, cannot be confined to chemical phenomena: the motions of those atoms and molecules underlie all our explanations of the physical cause of light and heat, and they are already taking up the field of magnetism and electricity. Consider, for example, the heat of gases, both as regards the motion of translation of the molecules which produce temperature, and the motions of rotation and vibration of their constituent atoms, which, though they do not express themselves as temperature, constitute a portion of the heat. Clausius has shown that, even in the simplest gases, nearly two-fifths of the whole heat is due to these internal motions; whilst in gases of complex molecular constitution, which condense on combining, the ratio of the total heat to the heat of temperature is still greater. The experiments of Regnault, which show that the specific heat of a perfect gas at a constant volume is constant, proves, as Clausius has shown, that the one kind of motion is proportional to the others. The lecturer had also referred to atoms of the same kind combining together, so that free oxygen and free hydrogen, being considered as composed of molecules each containing a pair of atoms, has certainly simplified the results. But it must not be forgotten that this combination of like atoms is generally different from that of unlike atoms. The union of oxygen with oxygen, or nitrogen with nitrogen, produces no such effects upon the luminiferous ether as the union of oxygen with nitrogen. With the same quantity of matter, the amount of *vis viva* sent forth as radiant heat may be augmented a thousand-fold, perhaps a million-fold, by the act of diverse combination. This act seems to carry with it a condensation of the ether to a dense atmosphere around the atoms. Had a cannon the power of gathering round itself a dense atmosphere, it would send forth a greater amount of *vis viva* as sound. A gun fired at Chamouni may be heard upon Mont

Blanc, while the same gun fired on Mont Blanc may not be heard at Chamouni, because the air in which the concussion takes place is denser in the one case than in the other. In the same way, the diverse atoms, vibrating in the denser atmosphere formed on combination, show their vast superiority as radiators over like atoms, which, except in such special cases as ozone, &c., are incompetent to produce a similar condensation. The speaker then asked them to echo the resolution so well put to the meeting by Professor Williamson.

ELECTRO-CAPILLARY ACTIONS.

IN a recent note on this subject to the Paris Académie des Sciences, M. Becquerel writes as follows:—

Electro-capillary actions depend on a principle which is of frequent application in organic and inorganic nature; they appear wherever two liquids, which are conductors of electricity and have an affinity for each other, are separated by a partition of capillary structure which the liquids enter in virtue of capillarity. The liquids then react on each other, and cause an electric current along the thin liquid layer adhering to the sides of the capillary passages, which acts like a solid conductor.

In order to constant intensity this must be constantly depolarised; and this condition is fulfilled when the elements deposited by electro-chemical action are removed by the meeting liquids.

This is an electro-capillary couple, and by means of it most metals may be reduced and other substances deoxidised. The metallic solution is placed in a cracked tube closed at the end, and this is plunged in a solution of monosulphuret of sodium. Two thick glass plates bound together may be used to hold the metallic solution.

The following experiment proves the conductive power of the sides of the crack when covered with liquid. If a concentrated solution of protoxide of lead in caustic potash be substituted for the solution of monosulphuret of sodium, this does not effect the reduction of the copper, the electromotive force being less than in the other case. But if an electric current from a nitric acid couple is caused to pass into the two solutions by two plates—one of copper, connected with the positive pole, and placed in the solution of nitrate of copper; the other of platinum, connected with the negative, and placed in the solution of plumbic potash—there is, shortly after, metallic copper deposited on that part of the crack in contact with the metallic solution, and on the opposite part peroxide of lead. The metallic solution is thus decomposed; the nitric acid has combined with the alkali, and the oxygen has peroxidised the lead. The current then becomes constant. The effect is the same as if a platinum wire were introduced to connect the two solutions, and the electric current passed by it only from the one to the other, the end of it in the metallic solution being the negative pole, the other the positive; and we may infer that the sides of the crack act in the same way as metallic electrodes. Before the deposit, oxygen and hydrogen are disengaged, one within, the other without the tube, and this must proceed from the decomposition of water. The disengagement increases with the deposition of the copper, as this deposit acts the part of conductor. Instead of a cracked tube, a tube closed at the lower end with parchment may be used, giving the same results.

The surface of a body covered with a thin layer of a liquid conductor of electricity adhering to it through capillarity, conducts like solid substances, though in a less degree. In a cracked tube, the internal and external surfaces, being only prolongations of the sides of the crack, ought to show the same physical properties as these; only that the sides of the crack being nearer the centres of chemical action, contribute more to the electro-chemical effect. The following experiment leaves no doubt as to this:—

The tube and vessel of the electro-capillary apparatus having been filled with water acidulated to 1-10th with sulphuric acid, and the air expelled by boiling, a platinum plate was put in each, and these plates were connected with the poles of several couples. The water was decomposed; and if the positive plate was in the liquid of the tube, small bubbles of oxygen formed on it and on the internal surface of the tube. We must therefore conclude that the glass surface acted as a positive electrode.

The electro-capillary couples already referred to are of a simple kind. We may increase the effect in the following way:—

We have seen that, when two solutions, one acid, the other alkaline, act on each other in a capillary space, that part of the capillary space in contact with the metallic solution is the negative pole, and the other the positive pole of the couple. The decomposing force of the current may be increased by aid of another current resulting from a similar chemical action. Communication is established between the two liquids by means of a curved tube (not capillary) containing a thick wick of asbestos, moistened previously with distilled water. The liquids rise on either side of the tube, meet, and react on each other; electricity is disengaged; the metallic solution sets free the positive electricity, the alkaline solution the negative, and the circuit is closed by the crack. Thus a current arises in the same direction as the electro-capillary current of the crack, and the force is increased. If the crack did not exist, or if the opening were not capillary, the two currents resulting from chemical action would destroy each other, going in opposite directions. The increase in force is in proportion to the diameter of the communicating tube.

This subject connects itself with the passage of blood in the arteries and veins, and the transformation of arterial into venous blood. In a previous memoir it was shown that the electro-capillary effects were produced in cracks of 0.030, 0.029, and 0.05 m.m. breadth, and the phenomena of hæmaturia take place in capillary tubes of similar diameter. As to the effects produced on contact of arterial and venous blood, we may suppose that the cause is, as in the phenomena we have been considering, electro-capillary. The sanguineous electro-capillary couple is constant, like the inorganic one: an indispensable condition of hæmaturia. This constancy arises from the fact that the electro-capillary current constantly removes from the arterial blood the oxygen contained in it, carrying it to the internal sides of the venous capillary tubes (which are positive), where it burns the carbonaceous matters and others which penetrate by infiltration.

It is not possible to verify the electro-capillary theory in a living being: and the conditions change after death; but the analogy of effects induces us to admit that of the causes.

EXAMINATION OF THE GASES OCCLUDED IN METEORIC IRON FROM AUGUSTA CO., VIRGINIA.

By J. W. MALLETT, Ph.D., M.D.,

Professor of Analytical and Applied Chemistry, University of Virginia.*

THE investigation by Graham of the gases given off by meteoric iron from Lenarto, in Hungary, when heated in a vacuum produced by a Sprengel-pump, excited much interest at the time of publication,† but does not seem to have been followed up by any similar examination of other meteorites. I have made use of pieces of the iron found about three years ago in Augusta Co., Virginia, the description and analysis of which were published by me in the *American Journal of Science* for July, 1871, in order

to repeat the experiment of Graham and ascertain whether similar results to his would be obtained. A large part of the work of the extraction and analysis of the gaseous contents of this iron has been done by two of the students in my laboratory,—Mr. F. P. Dunnington, of Baltimore, and Mr. J. B. Adger, of South Carolina,—to whom I am much indebted for their assistance.

Two preliminary experiments were made; the first with some shavings from the cutting of the iron upon a planing-machine; the second with a solid piece of the metal planed to smooth, clean surfaces, and quite free from any crust or scale. The shavings were subjected to the purification practised by Graham, namely, washing with a hot solution of potassic hydrate, followed by washing with distilled water and thorough drying. The solid strip of iron was not so treated, care having been taken to use no oil upon the tool employed in cutting it. Both specimens gave off gas readily when heated in the Sprengel vacuum, the amount in each case being larger in proportion to the bulk of the iron than in the experiment of Graham; and analysis showed that the same gases were present as those found by him, with the addition of carbonic anhydride in not inconsiderable amount.

The final experiment was made as follows, with great care, and with all precautions which could be thought of to avoid error.

A parallelopiped of iron was cut upon a planing-machine, from the largest of the three masses found (that spoken of as No. 1* in the paper above referred to), the work being done with special care, to avoid the least trace of grease being derived from the machine.

Not only was the cutting-tool itself made red-hot in the blacksmith's fire, hardened in clean water, and tempered and ground without contact with anything greasy, but every part of the machine-bed, set-screws, and frame, from which any risk was to be feared, was carefully cleansed, and paper used to cover the whole of the iron, except where actually borne upon by the tool. The piece of iron measured about 75 m.m. long, 16 m.m. wide, and 12 m.m. thick. It was cut from as solid a portion of the mass as could be found, and was quite bright upon the surface and free from crust, though traces of a very minute crack or fissure were barely perceptible at one end. The piece weighed 124.589 grms.; and as the specific gravity of the iron had been found to be 7.853, the volume was 15.87 c.c. A new and perfectly clean porcelain tube, with sound glaze, was used, heated by a small upright fire-clay furnace with good draught, through holes in the opposite sides of which the tube was passed. The fuel was charcoal, in pieces a little larger than a walnut. The Sprengel's pump had a fall-tube of about 1.34 metres long; its connections were made with great care, and were protected by outer casings of india-rubber tube, with the annular space between the tubes filled with glycerine. A plate of glass, floating on the mercury in the funnel at top, served to prevent the risk of air being carried down, as the metal was gently poured on through another and smaller funnel with narrow aperture.

A good vacuum having been obtained in the cold, lighted charcoal was placed in the furnace, and gas very soon began to come off.

It was determined to analyse separately that collected at the beginning, middle, and end of the process, in order to see whether the different constituent gases were given

* The results of ordinary analysis were.—

Iron	88.706
Nickel	10.163
Cobalt	0.396
Copper	0.003
Tin	0.002
Manganese	trace
Phosphorus	0.341
Sulphur	0.019
Chlorine	0.003
Carbon	0.172
Silica	0.067

* A paper read before the Royal Society.

† Read before the Royal Society, May 16, 1867.

off at the same or at different rates. The total amount obtained was 36.33 c.c., reduced to 0° C., and 1 metre pressure. This was divided into three portions, for analysis, as follows:—

				h. m.
A.	52.02	per cent of the whole	was collected in	2 30
B.	24.11	"	"	2 20
C.	23.87	"	"	9 40
	100.00			14 30

It will be seen that the greater part came off within the first two hours and a half; but the process lasted *fourteen hours and a half*, and was not entirely over at the end even of this time. The heat had been gradually raised from dull redness to something nearly approaching whiteness at the end of the time; and when the experiment was stopped, very small but still perceptible traces of gas were still coming off, though their appearance was immediately arrested whenever the temperature was allowed to fall but a little below the high point which had been reached.

The piece of iron taken out from the tube when it had become quite cold was found glazed by a thin film of fused phosphide of iron and nickel (Schreibersite), thickest on the edge which had been lowest, this phosphide having oozed out from the mass at the very high temperature used.

The tubes used to collect the gas during the first portion of the time occupied in the experiment were found slightly moistened on the inside, and the moisture, which had a distinctly acid reaction, was proved to contain hydrochloric acid, this having no doubt been derived from the chlorine existing in the iron in combination with that metal and with nickel.

Careful analysis of the gas yielded the following results by volume for the three portions separately collected: the fourth column of figures, obtained by summing up the three which precede it, gives the percentage composition of the whole of the gaseous matter extracted from the iron:—

	Portion A.	Portion B.	Portion C.	Total gas.
Hydrogen	22.12	10.52	3.19	35.83
Carbonic oxide ..	15.99	11.12	11.22	38.33
Carbonic anhydride	7.85	1.02	0.88	9.75
Nitrogen	6.06	1.45	8.58	16.09
	52.02	24.11	23.87	100.00

Other gases were tested for, but none could be found; no free oxygen could be detected, nor any compound of carbon and hydrogen.

From these figures it appears that hydrogen maintains about the same proportion to the other gases in A and B, but diminishes largely in C; that carbonic oxide increases in amount in B as compared with A, but remains about the same in relative amount in C; that carbonic anhydride diminishes throughout the whole continuance of the experiment; and that nitrogen falls off in B as compared with A, but largely increases again in C.

Contrasting the results with those of Graham, and noticing first the total volume of gas obtained from the iron, it becomes necessary to reduce this volume to the same standards of pressure and temperature employed by him. In the paper read before the Royal Society, as reported in its "Proceedings," I find no statement in regard to such standards; but, supposing it probable that the barometer at 30 inches and thermometer at 60° F. were referred to, I have calculated the volume of gas obtained in all from 15.87 c.c. of iron as equivalent under these conditions of pressure and temperature to 50.40 c.c., or 3.17 times the volume of the metal. This is a somewhat larger quantity than that of Graham, namely, 2.85 times the volume of the Lenarto iron used; but the time of heating was longer in the experiment now described, and the temperature attained probably much higher.

As to the nature and relative amount of the constituent gases, the results differ very noticeably from those of

Graham, as is evident when the figures of the two analyses are placed side by side.

	Lenarto Iron.	Augusta Co., Virginia Iron.
Hydrogen	85.68	35.83
Carbonic oxide ..	4.46	38.33
Carbonic anhydride ..	—	9.75
Nitrogen	9.86	16.09
	100.00	100.00

The gases obtained in the experiment now in question agree more nearly with those of common wrought-iron (clean horse-shoe nails) as found by Graham,* viz., in the first portion collected—

Hydrogen	35.0
Carbonic oxide ..	50.3
Carbonic anhydride ..	7.7
Nitrogen	7.0
	100.0

and the conclusion arrived at by him, that "the predominance of carbonic oxide in its occluded gases appears to attest the telluric origin of iron," would deny to the Virginia specimen the right to be classed amongst meteoric masses, with which, however, all its other physical and chemical characteristics agree most fully.

It is to be noted that the analysis of the gases from the Lenarto iron was not made with the whole of the gaseous matter collected: the first portion, amounting to about 32.5 per cent of all collected, was used for merely qualitative examination; the second portion, 57.6 per cent, was that fully analysed; while no mention is made of the disposition of the remaining third portion of 9.9 per cent; and it is stated that the iron was not fully exhausted at the end of 2 hours and 35 minutes, for which time only the experiment was continued. In my own experiment it appears probable that the amount of hydrogen (and with it the total volume of gas) has been slightly diminished by its union with chlorine of metallic chlorides, to form the minute quantity of hydrochloric acid observed in the faint film of moisture on the sides of the first tubes; and probably also this moisture itself may have been caused by the partial reduction, by means of hydrogen, of carbonic anhydride to carbonic oxide. Although it might be assumed, especially in view of the strong tendency of iron to take up and "occlude" carbonic oxide, that this gas had been the original form in which the gaseous carbon compounds obtained existed in the iron, and that it had in part broken up at the temperature of the experiment into carbon, remaining united with the iron, and carbonic anhydride which escaped as gas,—yet, in view of the steady decrease in the quantity of this latter gas collected as the experiment proceeded and the temperature became higher, and bearing in mind the ready decomposition it undergoes in contact with ignited iron, it seems more likely that a larger amount of carbon originally existed in the iron in this higher state of oxidation than appears from the figures of the analysis. Although the proportion of hydrogen found is so much less in the Virginia than in the Lenarto iron, it yet represents for the former about 1.14 times the volume of the iron itself, whereas common terrestrial iron occludes but about 0.42 to 0.46 of its own volume under ordinary pressure.

I am quite satisfied, from the condition of the masses of iron as they came into my hands, and especially from the character of the crust, that the metal has not been subjected to any heating in a blacksmith's fire or otherwise by human hands since it was found, as has sometimes happened to similar specimens in the endeavour to discover their nature, or to make use of them.

Whether or not this analysis be considered as furnishing

* Loc. cit.

presumptive evidence of the Virginia iron having come to our earth from a different atmosphere to that of which the Lenarto meteorite brought us a sample,* the result differs so far from that of our sole previously-recorded determination of the kind as to make it a matter of much interest that a larger number of meteoric irons, from various localities, should be subjected to careful examination in the same direction, thus supplementing our knowledge of the fixed constituents of these curious bodies by a study of their gaseous contents.

ON THE ACTION OF DILUTE SALINE SOLUTIONS UPON LEAD.†

By M. M. PATTISON MUIR, F.C.S.

It has been long known that water, which has been kept for some time in leaden cisterns, dissolves and holds in solution a certain amount of the lead forming the cistern. Pure rain or distilled water, it has been remarked, does this to a very notable extent, and in some waters—especially those containing nitrates—the amount of Pb thus dissolved is very considerable. Waters containing nitrates, and even pure waters, have thus exerted a poisonous influence on persons drinking them, such effects being in many cases clearly traceable to the lead held in solution by these waters. On the other hand, notice has been taken of the fact that the presence—even to a very minute extent—of certain salts in the water, especially sulphates and carbonates, tends to diminish the solvent action of that water upon lead; and hence, before using very pure waters, it has been customary in some places to add certain quantities of soluble carbonates and sulphates, in order that these may act as a check to the solvent action of the water upon the leaden pipes through which it may have to pass. It seemed that a somewhat more definite statement than is generally found in the text-books, as to the amounts of Pb dissolved in a given time by waters containing various salts in solution, might not be devoid of interest or of practical use. As the water supplying so many towns traverses—for longer or shorter distances—leaden pipes, and as even very small quantities of lead held in solution by a water largely used for domestic purposes must through time exert a hurtful effect upon those using it, to determine actually how much lead is dissolved by a water of definite composition, and how much of some foreign substance must be added to stop this solvent action, appears a not unimportant problem; nor would I pass over the value which any reduction of a chemical action to definite figures must necessarily and intrinsically possess.

At the suggestion of Prof. Thorpe I have undertaken some measurements of this action of water on lead, the results of which I shall now state.

500 c.c. of distilled water were poured into a clean flask, and, after a number of such flasks were thus filled, there was then added to each weighed quantities of various salts. Pieces of clean bright lead were then suspended by threads in these solutions, so that the liquid should have free access to all parts of the Pb; thus the surface of Pb acted on could be accurately determined. In these experiments, the surface acted on was = 5600 sq. m.m. The flasks were then set aside for 24, 48, and 72 hours, at the expiration of each of which periods the amount of Pb dissolved was estimated. To do this I employed a slight modification of the method given by Wanklyn and Chapman, in their book on "Water Analysis." This

process is essentially a colorimetric one, the amount of Pb present being estimated by the depth of colour given to the solution, on the addition of H_2S , as compared with the colour given to an equal bulk of pure distilled water, to which is added a known quantity of a standard Pb solution.

The standard Pb solution employed contained 0.1 grm. Pb per lit. of H_2O , so that each c.c. corresponded to $\frac{0.0001}{100} = \frac{1}{1000000}$ m.grm. of Pb. 100 c.c. of the solution to be tested were employed, and the reaction was of sufficient delicacy to detect easily 2 parts of Pb in 1,000,000 parts of water.

As to the composition of the solutions whose action has been tested, I have, in the first place, examined the action of Pb on solutions containing a determinate amount of only one salt in solution; then I have sought to answer the question—How would the addition of another salt act? would it retard or hasten the solvent action of the water on the Pb? If it retard this action, which salts, and how much of these, exercise such an influence to the most notable extent? If it hasten the solvent action, which salts do so in the greatest degree? Further, I have tried the action of a mixture of more than two salts in solution, thus approaching more nearly the conditions of an actual water. The results are embodied in the following table, in which the amounts of salts in solution in the water and the amounts of Pb dissolved are stated both in grms. per lit. and grs. per gall. :—

Salt.	Grms. per lit.	Grs. per gal.	Pb Dissolved. m.grm. per lit.			Pb. Dissolved grs. per gal.

The amounts of Pb dissolved in the same period of time, by waters containing different salts in solution, are thus seen to be very varied. Of all the salts whose influence upon the solvent action of pure water on lead was tested, nitrates—especially ammonium nitrate—increase that solvent action most largely. Perhaps the actual amount of nitrates generally present in water is not quite so great as that which I have experimented with, yet I would call attention to the fact that water containing the smallest quantity, viz., 0.02 grm. per lit., dissolved almost as much Pb as that containing double as much NH_4NO_3 . Again, it should be noted that generally as much, or almost as much, Pb was dissolved after 24 hours' action as after 72 hours; so that, in keeping a water in leaden cisterns for domestic purposes, although this water may never remain long in contact with the Pb, yet doubtless it would—if a water containing nitrates—dissolve in a short time hurtful amounts of that metal. The action of chlorides, at least of the only chloride with which I have

* Some of the observations of Secchi and Huggins seem to render it probable that carbon may play an important part in some regions of the universe, though the results on this head are not as full or satisfactory as those in reference to hydrogen.

† Read before the Glasgow Philosophical Society.

experimented (CaCl_2), seems to be a retarding, not a hastening action, as regards the amount of Pb dissolved: this has been noticed, both in the case of a water containing—as compared with distilled water—only chlorides, and also a water containing both chlorides and nitrates. Of those salts which have been experimented with, it is seen that the carbonates exercise a retarding action to the greatest extent; thus a water containing 0.31 grm. of K_2CO_3 per lit., = 21 grs. per gall., dissolves, after 72 hours' action on clean, bright lead, only about $\frac{1}{10}$ th of a gr. per gall. of water; or, in other words, the presence of 1 part K_2CO_3 in 3000 parts H_2O almost completely prevents such a water from exercising any solvent action on Pb. The soluble sulphates also exercise a very important retarding action, nearly as great—although not quite so—as that of the carbonates. If a water containing nitrates, even amounting to 0.02 grm. per lit., an unusually large amount, contain at the same time sulphates, as small a quantity as 0.05 grm. per lit., the solvent action of such a water on Pb. is thereby very much diminished,—diminished in the proportion of 13 to 2. The same deterrent action is exhibited by carbonates, with 0.045 grm. KNO_3 , and 0.308 grm. K_2CO_3 ; the amount of Pb dissolved, proportionately to that made soluble by a water containing the same amount of KNO_3 , but without any carbonates, was as 16 is to 0.3. The carbonates are thus even more beneficial than the sulphates, in the case of waters containing nitrates, and, as I before remarked, also in waters free from nitrates. When nitrates, carbonates, and sulphates are present together in a water, then the solvent action of this water on lead is almost *nil*. This is also the case if the sulphates or carbonates be replaced by chlorides, although in the latter there is a slightly greater action than in the former instance: thus, if to a water containing 0.02 grm. NH_4NO_3 per lit. be added double as much (0.06 grm.) CaCl_2 per lit., then the amount of Pb dissolved by this water is exceedingly small—about 1.1 m.m. per lit. in 72 hours. This action is one of some importance, as, generally speaking, water containing nitrates contains also chlorides, both perhaps coming from the same or similar sources.

From all these experiments I conclude that although we may, on analysis, detect a pretty large amount of nitrates, yet we must not hastily condemn such a water,—as far as its action on lead is concerned, I mean,—but must carefully determine whether there be not also such amounts of other salts—as chlorides, sulphates, or carbonates—present as shall, to a great measure, neutralise the hurtful action of the nitrates. Unfortunately we do not, as yet, possess reliable information as to the amount of lead which is positively hurtful to the vital economy; but we may perhaps say that a water containing 1 gr. per gall. would not generally be looked on with favour. That Loch Katrine water actually does exercise a solvent action on Pb cannot be doubted.

In my experiments, the amount dissolved by ordinary water, taken from the Laboratory tap, was 1 m.m. per lit. = $\frac{7}{16}$ gr. per gall. after 24 hours action of the water on a clean, bright piece of Pb. In 48 hours the amount of Pb in solution had not increased, and after a lapse of 72 hours the increase only amounted to about $\frac{1}{16}$ gr. per gall. As our cisterns are generally very far from being bright and clean, and as, after the first few hours, the solvent action diminishes very notably, we may conclude, I think, that the actual amount of Pb taken into the system along with the water we drink is not considerable. Does this amount of Pb thus gradually deposited in the system slowly find its way out again, or does it remain accumulating all through life? Does this in any way influence the general health of our bodies? May the healthiness of some places be influenced materially by the amount of Pb dissolved by the water in constant use? These are questions yet remaining to be answered—questions which are to be solved more by the physiologist than by the chemist.

ON OPTICAL PHENOMENA PRODUCED BY CRYSTALS SUBMITTED TO CIRCULARLY POLARISED LIGHT.*

By WILLIAM SPOTTISWOODE, LL.D., M.A.,
Treasurer R.S. and R.I.

ON a former occasion I exhibited some phenomena depending upon circular, or, as it was then also called, successive, polarisation, and in particular I adopted and explained a method for producing circularly polarised light devised by Sir Charles Wheatstone. I propose, on the present occasion, to pursue the subject into some of its ulterior consequences. In terms of the wave theory, light is said to be circularly polarised when the vibrations are circular, as distinguished from plane polarisation, when they are rectilinear. And further, it is known from mechanical principles that a circular vibration may always be produced by the combination of two rectilinear vibrations, the amplitudes or extents of which are equal, and whereof one is advance or in rear of the other by one or by any odd number of quarter-wave lengths. In the former of these cases the circular motion will take place in one direction, say right-handed; in the latter in the opposite, say left-handed. The contrivance I will now use for producing circular polarisation is known by the name of a "quarter-undulation plate," and consists of a plate of mica split to such a thickness that one of the two rays into which plane polarised light is divided on entering it is retarded by an odd number of quarter-wave lengths behind the other.

The optical phenomena produced by crystals, when submitted to polarised light, are usually divided into two classes, viz. (1), those arising from the use of parallel light, and consisting of broad sheets of colour; and (2), those due to convergent light, and consisting of the rings and brushes, the general character of which is well known. I propose to take a few specimens from each class, and to examine the modifications which the known phenomena undergo when the light is both polarised and analysed circularly, *i. e.*, when one quarter-undulation plate is interposed between the polariser (Nicol's prism) and the crystal to be examined, and the second between the crystal and the analyser (Nicol's prism).

In the first place, it is known that if a plate of selenite be placed in an ordinary apparatus when the polariser and analyser are either parallel or crossed, there are four positions, at 90° apart, in which the plate will produce colour; and further, that if the analyser be turned through 90° the same result will be obtained, except that the colour will be complementary to that first seen. The intensity of the light at any given point is then given by the formula—

$$\cos.^2 s - \sin. 2i \sin. 2(i - s \sin.^2 \frac{\theta}{2})$$

where i and s are the angles made with the original plane of polarisation by the principal sections of the crystal and of the analyser respectively, and θ is the retardation.

If, however, the two quarter-undulation plates (say the plates A and B) be introduced, the light undergoes the following processes:—First, it is plane polarised by the polariser; secondly, the plate A being placed so that its axis is inclined at $\pm 45^\circ$ to the original plane of polarisation, the light undergoes right- or left-handed circular polarisation, and in that condition falls upon the crystal; thirdly, in their passage through the crystal C the rays are each divided into two, whose vibrations are at right angles to one another, and whereof one is retarded in proportion to the thickness of C; fourthly, the plate B being placed so that its axis is parallel or perpendicular

* Read before the Royal Institution of Great Britain.

to that of A, each of these sets of rays is circularly polarised, one set right-handed and the other left-handed; fifthly, these two oppositely circularly polarised sets of rays combine, according to known mechanical laws, on emerging from B, into plane rays, in which the planes of polarisation, of the different colours of the spectrum are turned through different angles. Hence, finally, by turning the analyser round we shall cross these various planes in turn, and successively extinguish the different colours, leaving the complementary colours visible. The system of plates A C B consequently acts in this respect like quartz. It is, however, to be observed, that if the plate B be turned from one of the two proposed positions to the other, the directions of motion in the two emergent circularly polarised rays, and consequently the planes of polarisation of the different colours, will be reversed; in other words, with the plate B in one position we shall imitate a right-handed, with the plate B in the other a left-handed, quartz. The intensity of the light at any point is then given by the formula—

$$\sin^2 \frac{\theta}{2} \text{ for one position,}$$

$$\cos^2 \frac{\theta}{2} \text{ for the other.}$$

Again, if—the plates A B retaining either of the positions before indicated—the crystal C be turned round in its own plane, then, since the light emerging from A and B is circularly polarised, it has lost all trace of direction with reference to the positions of the polariser and analyser, and consequently no change of tint will be observed. The same is abundantly clear from the formula written above, because the only term it contains depends upon the retardation within the crystal C. This experiment was made by Airy.

If the plates A and B have their axes directed 45° on either side of the axis of C, and the three plates be turned round as one piece, the colour will remain unchanged; while, if the analyser be turned, we have the colours shown in the regular order. If the plates A and B have their axes directed at 45° on the same side of the axis of C, and the pieces be turned round bodily as before, the colours change in the same order as above, and go through their cycle once in every 90° of rotation; and if the analyser be turned in the same direction, the colours change, but in the reverse order. The explanation of this is to be found in the fact that, when the plates A and B are crossed, the retardation due by A is compensated by that due to B; so that the only effective retardation is that due to the crystal C. But upon this depends the rotation of the plane of polarisation: if, therefore, the polariser and analyser remain fixed, the colour will remain unaltered. When the plates A and B have their axes parallel there is no compensation, and the colour will consequently change. This experiment was made by Fresnel.

The mathematical expressions for the intensity of the light in the two cases respectively are—

$$\cos^2 \left(j + i + \frac{\theta}{2} \right), \text{ and } \cos^2 \left(j - i - \frac{\theta}{2} \right),$$

where i is the angle made by the principal sections of A with that of the polariser, and j that of the principal section of B with that of the analyser. The first expression is obviously unchanged when the angle between the polariser and analyser, viz.—

$$\frac{\pi}{2} + i + j,$$

is unchanged. It should be added that the rotation of the plane of polarisation, and consequently also the sequence of tints, does not follow exactly the same law in the above cases as in quartz.

We now come to the case of convergent light, that is,

to the phenomena of crystal rings. And let us examine the effects produced by the same argument as before, viz., two quarter-undulation plates, A, B, one in front and one behind the crystal C. To quote from Mr. Airy:—"The first thing that strikes us in this combination is that there is nothing, except in the crystal, that has any respect to sides. For the only incident light is circularly polarised; the only light allowed to emerge is circularly polarised. The appearance therefore of the coloured rings, &c., must be such as conveys no trace of any plane of polarisation, and must not vary as the crystal is turned round. In the common exhibition of the coloured rings the principal trace of the planes of polarisation is in the uncoloured brushes. In uniaxial crystals they form an eight-rayed star, composed of two square crosses, inclined at an angle equal to that between the planes of polarisation, every ray of which separates complementary rings. In biaxial crystals they compose two pairs of rectangular hyperbolas, the angle between whose asymptotes is the same as that between the planes of polarisation, and whose branches divide complementary rings. The two crosses, or two sets of hyperbolas, unite when the planes of polarisation are parallel or perpendicular. But in the case under consideration the rings exhibited by crystals will not be traversed by any brushes. Uniaxial crystals will exhibit circular rings without a cross; and biaxial crystals will exhibit complete lemniscates, without any interruption from curved brushes." And it is further to be noticed, as the formula given above indicates, that the centres of the rings will be bright or dark according as the analyser stands at 0° or 90° .

To pursue this matter further. Suppose that, the arrangements remaining otherwise as before, the analyser be turned round; then in any position intermediate to 0° and 90° the rings will be contracted and extended in opposite quadrants, until at 45° they are divided by two diagonals, on each side of which the colours are complementary. Beyond 45° the rings begin to coalesce, until at 90° the four quadrants coincide again. During this movement the centre has changed from bright to dark. If the motion of the analyser be reversed, the quadrants which before contracted now expand, and *vice versa*. Again, if the crystal (say positive) be replaced by another (say negative), the effect on the quadrants of the rings will be reversed. This method of examination therefore affords a test of the character, positive or negative, of a crystal.

A similar process applies to biaxial crystals; but in this case the diagonals interrupting the rings are replaced by a pair of rectangular hyperbolas, on either side of which the rings expand or contract, and the effect is reversed either by reversing the motion of the analyser, or by replacing a positive by a negative crystal, or *vice versa*. The experiment may then be made in biaxial crystals, by turning the analyser slightly to the right or to the left, and observing whether the rings advance towards, or recede from, one another in the centre of the field. In particular, if polariser and analyser being parallel, the plate A have its axis in a N.E. direction to a person looking through the analyser, the plate B its axis in a N.W. direction, and the crystal be so placed that the line joining the optic axes be N.S., then, on turning the analyser to the right, the rings will advance to one another if the crystal be negative, and recede if it be positive. The mathematical expression for the intensity of the light at any point P is in this case—

$$\frac{1}{2} (1 + \sin. 2j \cos. \theta + \sin. 2b \cos. 2j \sin. \theta),$$

where b is the angle between the principal section of C through P and the principal section of B, and j the angle between the principal sections of B and the analyser. This shows that when the polariser and analyser are parallel or crossed at 0° or 90° , and consequently $j = 45^\circ$ or 135° , the expression is independent of b , i. e., the intensity is the same throughout circles about the centre,

but that when the polariser and analyser are crossed we have an expression of the form—

$$1(\pm \sin. 2\delta \sin. \theta),$$

the sign of the second term depending upon the direction in which the analyser has been turned, and also upon the sign of θ , that is, upon the character (positive or negative) of the crystal.

The dispersion of the planes of polarisation, effected by the passage of plane polarised light through a plate of quartz cut perpendicular to the axis, may be rendered visible by interposing such a plate of quartz between the polariser and a uniaxial or biaxial crystal, when the analyser is at 90° , i. e., when dark brushes are formed. In this case the brushes cease to be black, and are tinged throughout with colour. The analyser must, however, be turned back or forward, according as the quartz be right-handed or left-handed, in order that it may cross in succession the planes of polarisation of the different coloured rays, and so produce the most vivid effects. The dispersion of the brushes by a plate of quartz may, however, be studied, by employing an additional polariser and quartz plate between the source of light and the whole system previously used. By turning this polariser round we extinguish each ray of the spectrum in turn, and tint the whole field with the complementary colour. The brushes will then appear to revolve about their centres as the tints vary continuously from one end of the spectrum to the other. If the polariser be turned still farther round, the tints which had changed continuously from red to violet, or *vice versa*, change suddenly from violet to red, or *vice versa*, and the brushes jump suddenly back to their original position.

This last optical arrangement may be employed to examine the more important phenomena of the dispersion of the optic axes produced, not by a quartz plate between the usual polariser and crystal, but by certain biaxial crystals themselves.

ON A RELATION BETWEEN THE SURFACE-TENSION OF LIQUIDS

AND THE

SUPERSATURATION OF SALINE SOLUTIONS.*

By CHARLES TOMLINSON, F.R.S., and G. VAN DER MENSBRUGHE.

(Concluded from p. 282.)

We now pass on to consider the second proposition, namely, that if on the surface of a supersaturated saline solution there be deposited a drop of a liquid of feeble tension, the drop spreads and crystallisation is determined. Now it is shown in Part II. that drops of ether, of alcohol, and of similar volatile liquids, as well as of certain oils, both volatile and fixed, spread over the surface of the solutions and act as powerful nuclei. On the surface-tension theory, a liquid such as ether, of which the tension = 1.88, or alcohol = 2.5, or wood-naphtha = 2.11, or oil of lavender = 2.9, must spread on the surface of a supersaturated solution of Glauber's salt, of which the surface-tension is as high as from 4 to 5.2. This is true in a large number of cases that have been observed, and so far the phenomena are consistent with the theory. But there are cases in which liquids of low tension, such as oil of turpentine = 2.2 to 2.4, and some varieties of castor-oil = 2.5, do not form films, but well-shaped lenses, and remain as such during many hours and even days. Quincke seems to have met with cases of this sort in his elaborate inquiry on the capillary phenomena of the common surface of two liquids,† and he endeavours to account for these exceptions to the general law, by the statement that if a lens-shaped drop of a liquid 2 (of low

tension) remain on the free surface of a liquid 1 (of much higher tension) without spreading itself out, then it is certain that in most, and probable that in all cases the free surface of liquid 1 is rendered impure by a thin layer of a foreign liquid 3. Now in experiments on supersaturated saline solutions, the flasks, the filtering apparatus, and the solutions must be, as already explained by one of us, chemically clean, so that in boiling and filtering a solution into clean flasks in which it is boiled up again, covered over and left to cool in the open air of the country, it is difficult to imagine the existence of such a film as M. Quincke refers to. Moreover, did such a film exist, the solution in cooling would probably become solid under its action. Indeed, this sometimes happens in the case of flasks that have been already used in experiments on the nuclear action of oils; for, however carefully they are cleansed, it may happen that one or two out of a dozen may not be quite clean, so that, in the cooling of a boiling solution, a film detached from the walls of the flask may spread over the surface with nuclear action. In order, if possible, to prevent the formation of such a film, the following experiment was made:—

Expt. 8.—A solution of 1 part of Glauber's salt to 1 of water, with the addition of a bit of caustic potash, was boiled and filtered into four clean flasks. When cold, a drop of castor-oil was deposited upon the surface of each of the solutions. It flattened at first, but soon recovered the lenticular form. There was no nuclear action during an hour. On gently shaking the flasks, the oil was diffused through the solution without nuclear action.

In an experiment described in Part II. fragments of stearine were scraped into a solution with immediate nuclear action. In such a case, the stearine furnished the film-forming material that produced the solidification of the solution. The solution was boiled with the stearine in it, and in cooling the stearine formed into solid disks without nuclear action, although the flask was frequently shaken. In this case the boiling solution had saponified or otherwise removed the film-forming matter, or, in other words, had made the stearine chemically clean.

There is also a difficulty in the case of oil of turpentine, as in the following experiment:—

Expt. 9.—A drop of an old but clear and bright oil of turpentine was deposited on the surface of a solution containing 2 parts of salt to 1 of water. The drop flashed out into a film, and the solution immediately became solid. The turpentine was now distilled, and a drop of the distillate was deposited on a similar solution, when it formed a well-shaped lens with no nuclear action, although the flasks were left out during several days.

Now the tension of the old oil first used is = 2.2, and had the effect of distillation been greatly to exalt the tension, the experiment would have been intelligible according to the theory; but on measuring it the tension was found to be only 2.4.

A somewhat similar case is given in Part II., in which an old oil of bitter almonds was strongly nuclear, while the same oil freshly distilled had no such action, but became converted into benzoic acid, still without any separation of salt. After some days, to prove that the solution was still supersaturated, it was touched with an unclean wire and it immediately became solid.

Still, however, there are such a large number of cases in which oils and other liquids spread upon the surface of the solutions with nuclear action as to justify the labour bestowed upon the theory by one of us during the last six months. Many of these cases are stated in Part II., but a few of them may be repeated here for the sake of comparing the action of such liquids upon solutions of different strengths which was not done before.

If we take a number of oils, the tension of which varies from about 2.5 to 3.5, a drop of any one of them, according to the theory, ought to spread on the surface of a solution where $t = 5.2$, and not in all cases spread on the solution of which $t = 4$.

Expt. 10.—Twelve flasks, containing a solution of

* A paper read before the Royal Society.

† *Pogg. Ann.*, cxxxix. See also *Phil. Mag.* for April, 1871.

1 part salt to 1 of water were prepared, and a drop of each of the following oils formed films with immediate crystallisation of the solutions, viz. pale seal-oil, sperm-oil, cotton-seed oil, and niger-oil. A drop of linseed-oil formed a lens, but this soon becoming ragged, crystals diverged from it. A drop of castor-oil formed a lens with no nuclear action.

Expt. 11.—Three of the above solidified solutions were heated over a lamp, boiled, and covered over. The oil collected on the surface in innumerable small disks. Next morning one of the solutions was found crystallised, and the other two became solid on gently agitating the flasks.

In this case as the solutions cooled down or were gently agitated the disks spread out into films with nuclear action.

Expt. 12.—A solution of 3 parts salt to 1 of water was filtered into twelve flasks, when a drop of each of the following oils deposited on the surfaces of the solutions, became lenticular without any separation of salt, viz. pale seal-oil, olive-oil, rape, castor-oil, croton-oil, niger, sperm, and cotton-seed oil.

So far this result is in accordance with the theory.

Expt. 13.—A solution of the same strength as in the last experiment was employed, when a drop of seal-oil, sperm, cotton-seed, and niger spread out into films with powerful nuclear action. Linseed- and castor-oil formed lenses with no such action.

Now it must be remarked that on the day when *Expt. 12* was made the weather was dull, damp, and cloudy, and during the time of *Expt. 13* the weather was bright and clear. Some years ago it was a matter of frequent observation to one of us, that the formation of cohesion-figures on the surface of water was much more rapid and decisive, with altogether finer and sharper results, in bright weather as compared with dull, damp, wet, or foggy weather. The same remark applies to the motions of camphor on water, and to those curious phenomena known as "camphor currents" and "camphor pulsations." Now in the production of all these phenomena, as has been shown by one of us,† surface-tension plays a most important part, and such tension is lowered in dull foggy weather probably by the condensation of the vapour of volatile matters contained in the atmosphere. A drop of a liquid under such conditions may not spread on the surface of water or of mercury, the latter being especially liable to such influences; whereas on a bright day such surfaces are particularly active, and experiments succeed which some hours or days before failed to produce the results expected.

Then, again, as pointed out by one of us in Part II., the viscosity of the surface, or of the drop of liquid placed upon it, may greatly interfere with the operation of the law by which a liquid B spreads upon the surface A. A supersaturated saline solution has a considerable viscosity of surface, which it retains for many hours after it has cooled down. In the course of about twenty-four hours the more watery particles come up to the surface and the tension improves, so that the same surface which may have sufficient tensile force to cause a drop of oil to spread upon it, might some hours earlier have retained it in the lenticular form.‡

There are also certain modifications to which oils, &c., are subject in consequence of the presence of ozone and other matters in the air, which may somewhat disturb

the results expected to be obtained from the action of surface-tension.

It was stated in Part II. that when an oil, &c., assumes the lenticular form, the solution may be agitated so as to break up the lens into a multitude of globules, and give the solution the appearance of an emulsion. In such a case the tensions of the two liquids are of nearly the same value; if not the agitation often produces crystallisation; but even in the former case it was stated that a sudden jerk will sometimes produce immediate solidification of the solution. Now taking the tension of the solution at 5.2, and that of oil of olives at 3.7, and the tension at the surface of separation of the solution and the oil-lens at about 2, then the sum $3.7+2$ is equal to the tension of the solution, and the spreading on the surface ought to be impossible, unless fine clear weather, absolutely clean vessels and solutions, and the absence of surface-viscosity, concur to increase the surface-tension of the solution. At the surface of separation of the solution and of the glass, spreading may be possible in the case of certain oils without these concurring circumstances. Suppose a drop or a minute globule of oil to be brought into direct contact with the wet solid side of the solution, as by the jerk above referred to, the film of solution is displaced and the oil can wet the solid side. It may happen that the tension t of the solution at the wall of the flask is greater than the sum of the tension t of the surface of separation of the solution and of the oil, plus the tension of the oil in contact with the solid side; that being the case, the instant solidification consequent on the jerk is accounted for.

It will be seen then that when the drop of oil, &c., remains as a lens on the surface, there is a diminution of tension at the surface of the solution in contact with the oil; but in such a case the tension is not sufficiently lowered at one point as to render molecular equilibrium impossible at this point, and so break up the whole system of supersaturation. But if the solution be agitated, so as to bring into contact with the surface of the glass a portion of the drop, there will still be diminution of tension at the surface of the solution in contact with the solid, and now the diminution is sufficient to produce crystallisation. Thus it appears that oils may act differently according as they alter the tension of the liquid freely exposed to the air, or the tension of the liquid in contact with the glass, which is not of the same value.

With respect to Proposition III. there is no difficulty. A liquid of considerable contractile force, such as pure water, produces no separation of salt in a solution of less contractile force. This explains a number of cases described in a note by one of us submitted to the Society in July last,* in which solutions exposed for hours together to heavy rain did not crystallise, unless the rain brought down a speck of soot or some unclean body that lowered the surface-tension of the solution. Indeed we know of no liquid of superior tensile force to that of the solution, and not acting chemically upon it, that has any influence in producing crystallisation.

Proposition IV. also agrees with the phenomena. A glass rod or other solid, more or less smeared with a film of a liquid of low tension, when brought into contact with the solution determines crystallisation by lowering the surface-tension. Such, then, is the function of a nucleus with respect to supersaturated saline solutions. If the solid be made chemically clean, it may be plunged into the solution without altering its tension, and hence there is no separation of salt. And here it may be remarked that such a case is possible that a crystal of the salt itself may be brought into contact with the solution without disturbing its tension, and hence be inactive. It has never been pretended that a crystal of the salt is not a good nucleus for a supersaturated solution of its own kind. All that has been stated by one of us is that, under special conditions, such a crystal may be lowered into the solution without acting as a nucleus.

* *Phil. Mag.* for December, 1869.

† "Sur la Tension superficielle des Liquides," par G. Van der Mensbrugghe.

‡ Some of the distinguished physicists who are now engaged in studying the phenomena of surface-tension refer to the embarrassing effects of surface-viscosity. Thus Herr Lüdige remarks that a solution of soap ($t=2.8$ to 3) does not spread upon a solution of Panamwood ($t=5.7$); and it has been shown by one of us that the viscosity of the surface explains why a solution of soap does not spread on solution of saponine or of albumen; and, on the other hand, the liquid drop being viscous, there is no extension, or only a feeble one, since the slight difference in tension is equilibrated by the resistance of the viscous liquid.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, May 27, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

Iron Contained in the Blood and in Food.—Dr. Boussingault. This exhaustive physiologico-chemical memoir treats on the part which iron plays in the animal as well as vegetable kingdom, and on the quantity of that metal present in the human body; in animals; in various vegetable substances; in water, wine, beer, and sea-water. This paper is elucidated by a series of tabulated forms, containing the results of experiments. It appears that the mollusks and other invertebrate animals contain almost as much iron in their blood as the vertebrate animals, while cryptogamic plants also contain a large proportion of the metal.

On an Aldehyde-Alcohol.—A. Wurtz. This essay contains a detailed account of the mode of formation, combinations, and products of decomposition, of a body derived from aldehyde, and which, at the same time, plays the part of an ordinary alcohol and of an aldehyde. The formula of this new compound—which is formed when a mixture of 1 part of aldehyde, 1 part of water, and 2 parts of hydrochloric acid, is left standing for some days—is $C_4H_7O_2$, and termed aldol by the author. At 0° this substance is a very viscous fluid, having a sp. gr. = 1.208; at a higher temperature it is as fluid as water: at above 100° it becomes decomposed, yielding water and crotonic aldehyde, C_4H_6O . Aldol reduces ammoniacal nitrate of silver and the cupro-potassic liquor; heated with anhydrous (glacial) acetic acid it is decomposed, yielding again water and crotonic aldehyde; it combines, however, with glacial acetic acid, when they are heated together on a water-bath for some days.

On a New Organic Base Derived from Sugar.—G. Bouchardat. By treating the bromhydrac and chlorhydrac ethers of dulcitol [$C_{12}H_{22}O_{11}$] with strong ammonia, the author has obtained a new organic base, which he terms dulcitamine, $C_{12}H_{21}NO_{10}$. The chlorhydrate of this base is prepared by heating to 100° for a period of 6 hours, 1 part of monochlorhydrac dulcitol, $C_{12}H_{21}ClO_{10}$, with 10 parts of a saturated alcoholic ammonia. When this compound, the chlorhydrate of dulcitamine, is treated with water and oxide of silver, dulcitamine is set free. This base is a powerful alkali, which even displaces ammonia from its combinations, and forms with acids neutral salts; the chlorhydrate of dulcitamine forms with chloride of platinum a crystalline compound, $C_{12}H_{21}NO_{10}HClPtCl_6$, insoluble in water and absolute alcohol, but readily soluble in ether.

On Bleaching-Powder.—P. Crace-Calvert. After first referring to Dr. Balard's researches on this subject (*Annales de Chimie et de Physique*, second series, vol. lvii., 1834), the author gives an account of his method of analysing bleaching-powder, and states that this material contains, on an average, 1 part of hypochlorite of lime to 2 parts of chloride of calcium. The author experimented with samples obtained from various chemical works.

Production of a Crystallised Phosphuret of Iron.—M. Sidot. By passing the vapours of phosphorus over incandescent piano-wire (iron), the author obtains, after re-melting the first product, a highly magnetic crystalline phosphuret of iron, containing in 100 parts—Iron, 87.9; phosphorus, 12.1; formula, Fe_3P .

La Revue Scientifique de la France et de l'Etranger,
June 1, 1872.

This number does not contain any original chemical papers, but we call attention to the following interesting memoir:—

History of the Observatory at Paris.—E. Yung. This paper is divided into the following sections:—Origin; period of the Cassinis (1671—1793); period of the Convention (1793—1795); period of the Bureau des Longitudes (1795—1854); period of independent directors (1854—1872). In a sense this paper proves "que la France intelligente, éclairée et libérale ne pérît pas," although the motto of the Parisian coat of arms, "Fluctuat nec Mergitur," applies to "la belle France" in many respects.

Continuation of the Lectures on Animal Heat.—Dr. C. Bernard.

June 8, 1872.

This number contains no original papers relating to chemistry, but we call attention to the continuation of the excellent lectures—

On Animal Heat.—Dr. C. Bernard.

American Journal of Pharmacy, June, 1872.

In addition to several important papers more particularly relating to pharmacy and pharmacognosy, this number contains the following original papers bearing upon chemistry:—

Citrate of Iron and Bismuth.—C. Rice. The author describes the preparation of a liquid which contains citrate of bismuth and citrate of iron together in solution, the first-named salt being dissolved in dilute ammonia; ammonio-citrate of iron is added, and then—in order to make the solution keep—either glycerine or, better still, good sherry wine is added. This preparation is largely used in the United States in dyspepsia.

New Process for Detecting Bromide in Iodide of Potassium.—Dr. E. van Melckebeke. If to a saturated solution of bromide of potassium a small quantity of pure iodide is added, it will completely dissolve, but if the iodide is contaminated with bromide of potassium this impurity will remain undissolved; 100 parts of water (distilled), at 16°, dissolves 140.10 parts of iodide of potassium, and the same quantity of water, at the same temperature, dissolves 63.39 of bromide of potassium; 100 parts of water saturated with bromide dissolve only 13.15 parts of iodide of potassium, and if more of that salt is added bromide is precipitated. As the solution of the salts in water causes a very sensible lowering of temperature, for testing the author recommends to dissolve pure bromide of potassium in warm water, to let this solution cool, and decant from the crystalline deposit. To 10 c.c. of this solution, 10 drops of water are added in a test-tube, and afterwards in small quantities, and, constantly shaking 1 grm. of the suspected iodide in coarse powder, if free from bromide it will dissolve almost instantly, while if bromide is present it will remain undissolved.

Annalen der Chemie und Pharmacie, No. 7, 1872.

This number contains the following original memoirs and papers:—

On Chrysianissic Acid.—Dr. H. Salkowski. Too extensive for useful abstraction. It is divided into the following sections:—Introduction, containing a review of the labours and researches of others on this subject; preparation of chrysianissic acid; properties and combinations of this acid; products of decomposition of this acid; re-formation (*Rückbildung*) of chrysianissic acid; its formation during its preparation; dinitro-aisic acid; constitution of chryso-anisic acid and substances isomeric with it.

Influence of the Potassa and Soda Salts upon Alcoholic Fermentation.—C. Knapp. After first referring, at some length, to the researches of physiologists on the action of the potassa salts upon the animal organism, the author details at length a series of experiments made with the view to ascertain the difference of action—if any—upon the process of fermentation of sugar solutions to which yeast is added. While it is evident, from these researches, that potassa salts accelerate the fermentation, while soda salts are inactive, the mode of action of the first-named salts is not precisely clear.

Researches on the Pigments Present in Bile.—R. Maly. The third and concluding portion of this monograph treats of the conversion of bilirubin into urine-pigment.

Preliminary Communication.—E. Linnemann. The main gist of this brief paper is, that the combination of acrylic acid with hydriodic acid is identical with the glycerin-iodopropionic acid.

Contribution to our Knowledge of the Cochineal Pigment.—C. Liebermann and W. A. van Dorp. This exhaustive monograph is divided into the following sections:—Introduction, containing an excellent review of the labours of others on this subject; nitrococcic acid; trinitro-cresol; binitro-amido-cresol; rufo-coccin; by-products of the preparation of rufo-coccin.

Researches on Isomerism of the Benzol Series.—F. Beilstein and A. Kuhlberg. The fourteenth instalment of this monograph. This part treats on cinnamic and benzoic acids; preparation of cinnamic acid; nitro-cinnamic acid; nitro-hydro-cinnamic acids; meta-nitro-benzoic acids; anthranilic and salicylic acids from metanitro-benzoic acids; nitro-*o*-toluyl acids; indol; nitrophenyl-chloroacetic acid; tyrosin.

Action of Active Oxygen upon Pyrogallol Acid.—H. Struve. This essay contains the detailed account of a series of experiments made with the view of ascertaining the action of oxygen (super-oxides) and ozonised oil of turpentine on pyrogallol acid. It appears that the last-named substance is completely converted into purpurogallin—a body described by Aimé Girard (*Zeits. krlft für Chemie*, 1870, p. 86).

On Water-Baths with Constant Level.—J. L. Smith. The detailed description of a contrivance for keeping water-baths—while in use in chemical laboratories—filled with a sufficient quantity of water.

Le Moniteur Scientifique Quesneville, May 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Essay on the Docimastic Extraction of the Bismuth Ores, and the Docimastic Method of Separating this Metal from Copper, Arsenic, Antimony, and Lead.—H. Tamm. This exhaustive memoir is divided into the following sections:—Assay of bismuth ore; assay of bismuth ores containing much copper, and extraction of the metal from such ore; method of separating, on the large scale, arsenic from bismuth; method of separating bismuth from antimony; method of separating copper, sulphur, and lead, from bismuth—all on the large metallurgical scale.

The Phosphates of Lime of Russia.—A. Yermoloff.—This paper, illustrated by a map exhibiting a portion of the Russian Empire, contains an account of the situation and extent of phosphate of lime deposits in that country. It appears that there are several very extensive deposits of native phosphate of lime, one of which occupies a surface of no less than 20,000,000 of hectares, each of which (≈ 2.471 acres) will yield some 14,000 tons of this mineral, which on an average has been found to contain, by analysis, about 20 per cent of phosphoric acid.

Best Methods of Analysis of Artificial Manures.—L. Fresenius, C. Neubauer, and E. Luck.—This monograph is divided into the following chapters:—Methods of estimating phosphoric acid in general; special methods of estimating phosphoric acid; estimation of precipitated phosphates in superphosphate of lime.

Bibliography.—Under this heading we quote the title of the following work, which is very highly spoken of in the periodical above-named:—"Chimie Organique Élémentaire," par Edouard Grimaux: Paris, Germer-Baillière, 1872.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
April 11, 1872.

Physical and Chemical Properties of Various Kinds of Brass.—C. Mène.—A tabulated form, exhibiting the chemical formulae, composition in 100 parts, sp. gr., atomic weight, colour of the fracture, breaking-strain in pounds, degree of ductility, degree of hardness, and degree of fusibility, of a number of alloys of copper and zinc.

Rapid Dryer (Siccatif) for Oil-Paints and Varnishes.—C. Mène.—In 100 parts of water are dissolved, by the aid of heat, 12 parts of best shellac and 4 parts of borax; this solution, after cooling, is poured into bottles, which should be well corked. According to the author, this solution may be mixed with some oil of turpentine, with oil-paints, to render them rapidly drying, while the liquid may also be employed as a varnish.

Glycerine as a Tanning Material.—C. Mène.—After first observing that glycerine is a substance which has been found by experience to be useful as a means of increasing the elasticity and strength of leather, the author states that leather (hides rather), first partly tanned by the usual process, may be greatly improved—especially if required for machine-belts—by being soaked for some time in glycerine.

Studies on Dynamometers.—C. Mène.—The continuation of an essay on this subject, copiously illustrated with woodcuts.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale,
No. 233, May, 1872.

The only original paper relating to chemistry met with in this number is—

Report on an Ink which does not Corrode Steel Pens.—Dr. Balard.—This exhaustive memoir contains much valuable information on inks in general. The use of inks of a similar composition to that now generally employed appears to be of more ancient date than is generally supposed, because the author mentions, in the historical introduction to his report, that on examining a manuscript of the year 910, and belonging to the papers of the Cluny Abbey (Paris), it was evident that the ink it was written with was similar in composition to that now in use: it further appears that M. Couplier and Collin have succeeded in preparing an ink which very nearly answers to the conditions required by the Society for its prize medal, which, however, has not yet been granted to M. Couplier and Collin, though in order to encourage their labours a sum of £20 has been awarded them. This ink is well worthy of general notice, as it is not acted upon by nitric and hydrochloric acids, chlorine, or bromine; it is, however, not quite proof against alkalis.

Gazzetta Chimica Italiana, Nos. 2 and 3 (double number), 1872.

This number contains the following original papers and memoirs:—

On Anisic and Methylsalicylic Alcohols.—S. Cannizzaro and W. Koerner.—The authors give an account of their researches on the anisic alcohol as compared with the therewith isomeric methylsalicylic alcohol (methylsaligenin). The first-named product has been prepared by the action of alcoholic potassa upon anisaldehyde, while the methylsaligenin is prepared by adding to a solution of saligenin in wood-naphtha the requisite quantity of potassa to form first—

which is next boiled with iodide of methyl. Methylsaligenin is at the ordinary temperature an oily fluid which is difficultly solidified when exposed to the action of a mixture of solid carbonic acid and ether; anisic alcohol is crystalline, and fuses at 25°.

Anisic-alcohol.	Methylsaligenin.
Boiling-point 258.8° at 760 m.m.	Boiling-point 247.5° at 765 m.m.
Sp. gr. at 26° = 1.1093	Sp. gr. at 23° = 1.1200
" " at 100° = 1.0507	" " at 100° = 1.0534

Measurement of the Index of Refraction of Anisic and of Methylsalicylic Alcohols.—P. Blaserna.—An algebraico-optical essay.

Detection of Iodine when Present in Urine in the State of an Iodide.—Dr. P. Pelloggio.—The main gist of this essay is that, according to the author's researches, electrolysis of iodine containing fluids, previously mixed with hydrochloric acid and starch-water, is the most sensitive method for detecting very small quantities of iodine.

Nature of the Colouring Matter met with on the Urn of St. Ambrosius, at Milan.—R. Frapolli, R. Lepetit, and P. Padulli.—On the urn of St. Ambrosius,—dating from the ninth century,—being recently opened at Milan, it was found to contain along with earthy matter some colouring substance, which, on being tested by the authors, was found to consist of indigo and shellac.

New Method for Detecting Fuchsin.—G. Romei.—The author refers at considerable length to the researches of various authors who have devised methods for detecting fuchsin in syrups, sweets, &c. It appears that wines are also sometimes artificially coloured with fuchsin; and the author proposes to treat the wines with amylic alcohol after previous treatment with acetate of lead for precipitating the peculiar wine-colouring pigment.

Chemico-Microscopic Research of a Peculiar Substance which Accompanied the Meteoric Dust which Fell in Sicily on 9th, 10th, and 11th March Last.—O. Silvestri.—The peculiar substance, designated popularly as blood-rain, was found to consist in 100 parts of red iron ochre, 75.1; carbonate of lime, 11.7; organic matter, 13.2.

Programme de la Société Hollandaise des Sciences de Haarlem, 1872.

From this paper we learn with pleasure that an Englishman has had awarded to him the first "Boerhaave" medal—the gentleman being Mr. H. Clifton Sorby, F.R.S., of Sheffield, who has obtained this distinction for his excellent microscopical researches in reference to mineralogy and geology. Mr. Sorby has been elected one of the foreign members of this ancient scientific institution, an honour likewise conferred upon Dr. C. A. Würtz of Paris, and the Right Hon. Lothrop Motley, temporarily residing at the Hague. We quote from this programme the following prize-questions relating to chemistry:—To be answered on or before 1st January, 1874: To study in detail the influence which physical and chemical modifications of the dissolving agent exert upon the form of carbonate of lime when it is deposited from aqueous solutions; what are the chemical changes which stone-bearing fruits undergo during their development? to be elucidated by original chemical researches and analysis; to find satisfactory means for determining the temperature, degree of hygroscopicity, and the density of the atmospheric air at a considerable distance above the earth's surface; these means ought to be either such that automatic registration is possible, or so contrived that the observations can be frequently repeated. In addition to the gold medal (the ordinary prize) a sum of £25 will be awarded for satisfactory answers to this question.—To be answered on or before 1st January, 1873: Exactly-made determinations of the density (sp. gr.) of pure water free from air at different temperatures expressed in degrees of the air thermometer; quantitative chemical analysis to be made of different kinds of glass of which the co-efficient of refraction is known; new researches to be made on the liquids and gases occluded in small cavities of native crystals. The memoirs to be written (not, however, in the handwriting of the authors) in Dutch, Latin, English, French, Italian, or German languages (not with German characters), and to be accompanied by a sealed note, bearing inside the author's name, and outside a motto, also to be written on the fly-leaf of the memoir, to be sent, carriage or postage paid, to Dr. E. H. von Baumhauer, secretary of the Society at Haarlem, Holland. The sealed notes of the memoirs to which no prize is awarded are destroyed unopened unless the memoir is found to be a copy or abstracts from printed works. The ordinary gold medal of the Society, the prize awarded, has an intrinsic value of £12 10s., while in some cases that sum is added to the medal.

Les Mondes, June 6, 1872.

This number contains no original papers relating to chemistry or collateral matters.

NOTES AND QUERIES.

Iodine.—I wish to estimate the percentage of iodine in such products as kelp. Can any reader kindly recommend a method combining quickness and accuracy?—J. S.

Salts of Chromium.—I am anxious to learn whether it is possible to make salts of chromium perfectly free from iron either commercially or as laboratory specimens?—CHROMIUM.

MEETINGS FOR THE WEEK.

MONDAY, June 24th.—Royal Geographical, 8½.
WEDNESDAY, 26th.—Society of Arts, 4.
THURSDAY, 27th.—Royal Society Club, 6½ (Anniversary).
Philosophical Club, 6.
FRIDAY, 28th.—Quekett Club, 8.

TO CORRESPONDENTS.

T. R. Y.—Cooley's "Cyclopedia of Practical Receipts" is published by Messrs. J. and A. Churchill, price 28s.

J. Parry, W. Thorp, jun., S. E. Phillips.—These correspondents are thanked for their communications, which shall receive attention.

THE CHEMICAL NEWS.

Vol. XXV. No. 657.

ON THE
OXIDATION BLUE OF BOLETUS CYANESCENS,
B. LURIDUS, &c.,
AND ON A
SIMILAR PRODUCT DERIVED FROM PHENOL.

By T. L. PHIPSON, Ph.D., F.C.S., &c.

IN a former paper* I attributed the intense blue colour produced by hypochlorite of lime in the alcoholic solution of the yellowish colouring matter of *Boletus luridus*, &c., to the presence of phenylamine (aniline) in the tissue of these fungi; though, in the absence of sufficient data relative to the composition of the colouring matter, this opinion was put forth as little better than a conjecture.

Recently a paper on the same subject has been published by Mr. H. Ludwig,† whose method of experimenting has not enabled him to detect aniline, though he has convinced himself of the presence of nitrogen in the colouring matter; and had he pushed his investigation a little further, I am convinced he would have obtained some phenyl derivative also.

I have more recently obtained, artificially, a blue colour exceedingly like that yielded by oxidation of the freshly-cut surface of these *Boleti*. A small quantity of ordinary phenol is dissolved in methylic alcohol saturated with ammonia. To this, hypochlorite of lime is added cautiously, in small quantities, until an intense blue colour is produced. This is soluble in water. The aqueous solution, considerably diluted and acidified by hydrochloric acid, is reddish or pinkish, but after a while deposits a small quantity of a dark resinous substance, and then it is a clear yellow solution, which in presence of ammonia takes a blue colour, in a very few minutes, by contact with the air.

This yellow solution, to which a few drops of ammonia have been added, behaves exactly like the freshly-cut surface of *B. luridus*, and the ephemeral blue colour produced is very similar to that of the fungus, though they may not be absolutely identical in composition. Nevertheless, this experiment induces me still to believe that the blue colour derived from *Boletii* belongs to the phenyl group.

ESTIMATION OF CARBON IN PIG-IRON,
WROUGHT-IRON, AND STEEL,
BY
COMBUSTION WITH OXIDE OF COPPER
IN VACUO UNDER SPRENGEL PUMP.

By JOHN PARRY, F.C.S.

IN the course of experiments now in hand, with the view of estimating the amount and kind of gas occluded in pig-iron, &c., it was thought necessary to heat the iron with oxide of copper *in vacuo*, and it was found that accurate carbon determinations could be made as follows:—

(1). Digesting the metal in solution of CuSO_4 , filtering and washing residue of precipitated copper mixed with the carbon through asbestos.

(2). The dried residue mixed with about 50 grms. pure oxide of copper, and placed in a combustion-tube sealed at

* "Sur les Bolets Bleuissants, &c." Bruxelles, *Journ. de Méd.* 1860 (and, same year, *Comptes Rendus*, Paris, "De la Présence de l'Aniline dans certains Champignons.")

† *Journ. of the Chem. Soc. Lond.*, May, 1872, p. 424.

one end and drawn out at the other, the drawn-out end being fitted into a water-joint connected with the pump, as shown in Frankland and Armstrong's Memoir (*Chemical Journal*, vol. vi., p. 90). A vacuum being first formed, the tube was heated to a red-heat until gas ceased to be evolved. The gas was collected in a carefully-calibrated gas-tube, and measured with the usual corrections for temperature, pressure, and moisture, the amount of carbon being calculated from the number of c.c., measured according to Bunsen. Several trials were made with iron direct mixed with CuO , but all failed to give the full amount of carbon.

A sample, ascertained to contain 3.2 per cent carbon, kept heated under pump for more than 12 hours, gave only 2.97 carbon, with CO_2 gas still being evolved. Other trials—heat kept on from 2 to 4 hours—gave 2 to 2½ per cent carbon.

It was found, in all cases, that the gas given off *in vacuo* consisted entirely of pure CO_2 , but that care was necessary to insure the perfect purity of the CuO used and freedom from dust.

Expt. 1.—A grey pig-iron. 1 grm., heated 1 hour under pump, gave 59.8 c.c. CO_2 = carbon 3.206 per cent; ditto, by ordinary combustion with CuO in current of O, carbon (1) 3.280, (2) 3.264. To experimentally test the calibration of the gas-tube a light glass flask, about 100 c.c. capacity, was fitted with a capillary tube and glass stopcock. This was connected with the pump, and the air having been exhausted the stopcock was closed, the apparatus detached from the pump, and weighed. By passing the capillary tube up the tube containing the gas, and opening the stopcock, the CO_2 gas was drawn into the flask.

First weight exhausted flask .. 23.274 grms.

Second weight with CO_2 drawn in 23.333 " CO_2 0.059

Carbon 3.206 per cent.

Expt. 2.—Another sample grey pig-iron. (1). Ordinary combustion, carbon 3.600 per cent. (2). Under pump, gas pumped direct into weighed KO bulbs, carbon 3.654 per cent.

Expt. 3.—It being thought probable that by ordinary combustion CO_2 might be retained in the oxide of copper, 1 grm. of a grey pig-iron was treated with solution of CuSO_4 , washed, &c., mixed with CuO , and placed in a combustion tube, drawn out so as to admit of detaching the O-generating apparatus, and, readily sealing the end in the blowpipe flame, gave carbon 3.228 per cent. The O apparatus was detached, the tube sealed up and allowed to cool; when cold the tube was attached to the pump, exhausted, and again heated. A considerable quantity of gas was given off, which was found to be pure O, without the slightest traces of CO_2 and CO.

Expt. 4.—Puddle bar, described as being thoroughly puddled iron. Ordinary combustion, carbon (1) 0.143 per cent, (2) 0.131 per cent. Combustion *in vacuo*, carbon 0.1465 per cent.

Expt. 5.—Wrought-iron armour-plate. Combustion *in vacuo*, carbon 0.1426 per cent.

Expt. 6.—Steel. Combustion *in vacuo*, carbon 0.2972 per cent. Eggertz's colour test, carbon 0.2800 per cent.

It appears, therefore, that the ordinary combustion method with CuO in O gas gives fairly accurate results. The author is, however, of opinion that more *sure* results may be obtained by the use of the Sprengel pump; and although the method appears more tedious, and requires some manipulative skill, yet, if the pump be properly fitted up and the gas-tubes carefully calibrated, combustions may be made with great facility.

Ordinary combustions require the undivided attention of the operator, and, from the number of parts, considerable care in guarding against leakage; moreover, the KO bulbs present a considerable surface for the deposit of dust and moisture.

With the pump, the vacuum once being secured and preserved to the end of the combustion, there is no fear of error from leakage, and the operator—having the CO_2 gas in the tube—can leisurely verify his measurements, &c., and also test the gas for CO_2 by passing up a potash ball, and, provided pure CuO is used and the combustion-tubes are clean, can absolutely depend upon first results. As far as the author's experience goes, such is not the case by the ordinary method.

When a careful determination of carbon in steel or wrought-iron is required, two trials must always be made; the writer, as a rule, makes three determinations by the old method.

Chemical Laboratory, Ebbw Vale.

ON CERTAIN NEW PHENOMENA IN CHEMISTRY.*

By VERPLANCK COLVIN.

THE subject of this paper is so broad and varied, the phenomena so interwoven and connected with different branches of material science, that the title is but a slight index to its character, and the paper itself can be only a brief statement of facts, with such deductions as may seem to follow. It might have been entitled "An Account of Mercury and its Amalgams." As that, however, is not exactly the scope of the paper, nor the final object of it, but only the means or vehicle of communicating some ideas—which I hope will prove to be new—it may be allowed to stand here as a suggestion as to the character of the matter which is to follow.

With the discovery, by Sir Humphry Davy, of the metals of the alkalis and earths, a new era opened in chemistry. The sombre clouds which non-experimenting theorists had cast around the science were suddenly and violently dissipated in the blaze of simple truth, and one of those epochs occurred which must from time to time recur, as man acquires mastery over matter. As the theories of Stahl and his *phlogiston* had been pressed down and swept away by the discoveries of the previous century, so the accumulated errors of the intervening age were overthrown by Davy's investigations, and the new metals were evolved by electrolysis in the form of amalgams or compounds with mercury. A few of the metals of the earths, however, could not be thus procured, and their existence was only rendered probable by the analogous action of their salts or oxides when under similar treatment. These discoveries not only gave to chemistry a list of new metals, but with every one actually evolved a new amalgam. Thus, to the list of amalgams known to the ancients, were added numerous new compounds, while the general character of the elements so associated was of the most dissimilar kind. One property only seems peculiar to the majority of them, softness or malleability, and ductility. To this class of easily amalgamated elements belong such old metals as gold, silver, copper, tin, and lead; and such new metals as potassium, sodium, and calcium.

The other class of metals is peculiar in combining but slightly or not at all with *pure* mercury; and these metals, like those in the preceding class, seem to have but one general characteristic, the reverse of that of the first class, hardness, and at times even brittleness.

Iron, probably, alone of all the metals known to the ancients, belongs to this second class; while of the new metals which seem to belong to it, chromium, columbium, titanium, manganese, zirconium, and perhaps rhodium, are examples. Singularly enough platinum and aluminium, malleable and ductile metals, appear to be attached to this class by reason of the difficulty experienced in directly combining them with pure mercury. It is therefore plain that the proper classification of metals as regards their affinity for mercury is their separation into these two

divisions; the *first* consisting of metals that readily combine with pure mercury; the *second* consisting of metals which refuse to combine with pure mercury, at a moderate temperature.

One of the consequences of the discoveries of Sir Humphry Davy, was the application of the amalgams of potassium and sodium to purposes of exploration in chemistry. Berzelius and Pontin obtained their ammonium amalgam by the direct electrolysis of aqua-ammonia in contact with mercury. But afterwards it was observed that this amalgam could be made by the action of potassium or sodium amalgam upon chloride of ammonium. It has been stated that the amalgams thus procured are not exactly similar, the amalgam prepared by the method of Berzelius having a composition according to H. Davy of one part of ammonium to 753 of mercury, and crystallising in cubes when cooled to zero centigrade; while that prepared with the aid of potassium and sodium amalgam contains according to Gay-Lussac and Thénard, one part of ammonium to 1800 parts of mercury.

The discovery by Graham of the metallic nature of hydrogen gas, as evinced by its occlusion in, or alloys with, palladium and platinum, enables us to avoid the difficulty of believing in the existence of a metal or "element compounded of gases"—which is an hibernicism—by supposing ammonia to be an alkaline nitrogen salt of the metal hydrogenium. Then, allowing that the light cellular or frothy state of the so-called ammonium amalgam is owing to the existence throughout the mass of molecules of released nitrogen, clinging to, and re-combining with, the rapidly re-oxidising hydrogenium, we account for the ammoniacal gas afterwards given off. We might then suppose that hydrogenium is the metal of the volatile alkali, ammonia, having little resemblance to magnesium, which Graham believed to most resemble it. This, however, is only an hypothesis, and is indeed a digression.

The potassium and sodium amalgams enable us to form, besides this hypothetical amalgam, compounds of mercury with those metals which I have arranged in a second class, as refusing to combine with pure mercury at a moderate or low temperature. The process is simply placing potassium amalgam, or its substitute, excited with some corrosive gas, solution of a salt, aqua-ammonia, water or acid (as the case may require) in contact with the metals to be amalgamated. A triple amalgam of mercury, potassium or sodium and "ammonium" (hydrogenium?) is sometimes useful; and I have found zinc amalgam, excited with chlorhydric acid, a powerful agent in producing these results.

And now, before proceeding to describe those phenomena of the discovery of which I can find no record, it is advisable to examine into the nature of mercury and its amalgams, and the present state of our knowledge of its compounds.

Remembering that the fluid mercury with which we are familiar is but the molten substance of a solid ductile and malleable metal, we arrive at the conclusion that amalgams are simply the *alloys* of mercury, as metals dissolved in melted lead would be alloys of lead. Now the alloys of mercury are peculiarly easy to examine; for even when in the fluid state they do not burn one's fingers, and by analysing amalgams we are able to discover the condition of the metals contained in them. Having prepared an amalgam of gold and dissolved it in an excess of mercury, I treated the fluid amalgam with nitric acid. When the quicksilver had entirely dissolved, there remained a small spheroid of gold, dark upon the surface, and when broken apart under the hammer, exhibiting a radiating crystallisation like that of globular iron pyrites. This, and other experiments (which I have not time to describe), appear to prove that a metal when amalgamated is really dissolved; and it is possible that if the reduction of the amalgam had been less rapid, a well-formed crystal of gold might have been obtained. The metals of the second class seem also to be actually dissolved in the mercury.

* A Paper read before the Albany Institute.

Our knowledge of the compounds of mercury, as derived from the latest standard works on chemistry, is singularly imperfect. Ste.-Claire Deville, the famed chemist of the late French empire, the discoverer of the economic process of aluminum manufacture, asserts that metallic aluminum is not susceptible of amalgamation. Prof. W. A. Miller, in his "Inorganic Chemistry" (third edition, p. 425) also says of aluminum:—"It does not combine with mercury." Yet in Watts's "Dictionary of Chemistry," published in London three years previous to this record in Miller, we find that, "According to Cailletet (*Comp. Rend.*, 44, p. 1250) aluminum (also iron and platinum) may be superficially amalgamated by contact with ammonium or sodium amalgam and water; also when immersed in acidulated water, in contact with metallic mercury, forming the negative pole of a voltaic battery." This, published in London, 1865, appears to ante-date the discovery of the method of amalgamating aluminum with the aid of sodium amalgam by some two years; but both discoveries are obviously genuine. Again, both Miller and Watts seem not to be aware of any method of combining mercury directly with metallic platinum, in the form of foil or wire, and describe an indirect method of obtaining it, by the electrolysis of chloride of platinum. Yet potassium or sodium amalgam will readily effect the combination. A few years since, while experimenting with the amalgams of the alkaline metals, I observed that a common iron nail which happened to fall into the amalgam, became coated with mercury. For a time I believed myself the discoverer of iron-amalgam, but on examination I have found mention of it more than thirty years upon record. Aiken (*London Phil. Mag.*, xiii., p. 416), shows that it may be accomplished with the aid of zinc amalgam and a solution of chloride of iron. Watts says (*l. c.* iii., p. 887), "Mercury and iron do not unite readily. A viscid amalgam is, however, obtained by immersing sodium amalgam, containing one per cent of sodium, in a clear saturated solution of ferrous sulphate. Joule (*Chem. Gaz.*, 1859, p. 339; *Chem. Soc. Journ.*, xvi., p. 378), has obtained amalgam of iron by electrolysis of a solution of ferrous sulphate, the negative pole being formed of mercury." None of these authors appear to be aware of any method of directly amalgamating iron, yet H. Davy distinctly states that either potassium or sodium amalgam will effect the union of mercury with iron and platinum.

Mercury has been employed from time immemorial, in separating the precious metals from their earthy associates. Originally the *pure* metal was employed, as indeed it still is to a considerable extent, held in little rifts or gutters in the trough or sluice where they washed the auriferous sands or pounded ore. This was also the method of amalgamation at the stamp-mills, and it is notorious that much gold passed over the mercury in this process, and escaped. Recently I observed in the gold mining regions of the Rocky mountains, at Central city and Nevada, Colorado, that for the rifts and gutters filled with mercury, they had substituted sheets of copper, superficially amalgamated, over which the ore reduced to a thin mud, or muddy water, was washed, its gold parting and adhering to the surface of the amalgamated copper, and doing so more readily than it would to the surface of pure mercury.

Here we have another instance of that *combination-action* which we have already noticed in the potassium and sodium amalgams, as evinced by their power to unite mercury with the metals of the second class. It appears that those metals of the first class which are softest, lightest, and most easily oxidised (as potassium, sodium, zinc, &c.), have the power to enable the harder, heavier, and least oxidisable metals of the same class (as copper, silver, and gold), to combine more readily with mercury than they would unassisted; and, further, to enable mercury to combine with the metals of the second class, which though generally harder and more brittle than any of the preceding, are often

readily oxidised. This *combination-action* separates the alloys of mercury from all other alloys, so far as we now understand them; for, as I have already shown, instead of the mercury always losing power as a metal solvent in proportion as it becomes alloyed—it shows a preference,—and when combined with portions of the readily oxidisable metals, becomes more active and indeed almost ferocious in its appetite for the metals and alloys that are of a highly electro-negative character; while if alloyed with sufficient gold or silver in the first instance, it appears satisfied, phlegmatic, and indifferent to further metallic food. Experiments which I have made demonstrate that cyanide of potassium *does not* answer as well as the amalgams of the alkaline metals, in effecting the union of mercury with electro-negative metals, as some have asserted. Its solution is, indeed, not more effective than aqua-ammonia in producing such results, and what efficacy either of these solutions possess may be attributed to their cleansing the surface of the metal to be amalgamated.

It now becomes evident that the separation of metals into the two classes is incorrect, as we have here, as in every other general classification in science, no absolute division, but merely extremes and means; the true mean being difficult to determine. The reactions of these amalgams of the electro-positive metals with those metals which are relatively electro-negative, are very instructive. They tend to prove that all the amalgams subsequently formed are the results of *electrical action*, to induce which we have only to place a particle of iron in contact with potassium amalgam and with water. In an instant we have a voltaic battery in active operation; the amalgamated potassium forming the "zincode," while the iron is the electro-negative element of the battery. Of the metals present the mercury is the electro-mean, and with the oxidation of the potassium, it passes over to and effects a combination with the iron.

Thus we arrive at a more correct classification, and at a law of preference of metals and alloys for mercury:—

1st Law.—Metals that are easily alloyed with mercury give place to and assist the less amalgamatable metals in combining with mercury, when in the presence of an acid or corrosive liquid or atmosphere, which attacks the metal already amalgamated, and which does not attack, or does not so violently attack, the metal to be amalgamated.

2nd Law.—The more intense the action of the acid or corrosive liquid or gas upon the metal in the original amalgam, the more rapid the formation of the secondary amalgam.

3rd Law.—The amalgams of electro-positive metals assist those metals which are relatively electro-negative in combining with mercury.

These laws are the results of certain experiments which, as examples, I will now proceed to describe and illustrate. Placing before us mercury—1st, in the pure state; 2nd, amalgamated with copper; 3rd, zinc amalgam; 4th, aluminum amalgam; 5th, sodium amalgam; 6th, potassium amalgam; and 7th, "ammonium amalgam" (hydrogenium?)—we may suppose that we have the extremes and some of the means of mercurial power; mercury in the *pure passive* and in the compound induced *active* state. To prove that it has a passive and an active condition, it is only necessary to exhibit gold leaf before the pure mercury and each of the several compounds mentioned.

First.—It will be seen that with mercury alone it does not readily amalgamate, and there is no attraction of the gold leaf toward the metal.

Second.—Held above the amalgamated copper there is no attraction, but the moment the gold is allowed to touch the surface, it is eagerly seized and devoured.

Third.—Held above zinc amalgam excited with chlorhydric acid, the gold leaf begins to waver and tremble slightly as though influenced by the amalgam. Touched to the amalgam it is seized and vanishes instantly.

Fourth.—Above the sodium amalgam, excited with water or aqua-ammonia, we have the same symptoms, but even more excitement and eagerness on the part of the gold leaf to pass to the amalgam as it is approached; and the gold is scarcely touched ere it is gone, licked up by the hungry amalgam.

(This action is only seen when but short distances intervene between the gold leaf and amalgam, an eighth or sixteenth of an inch. To perform the experiment successfully, the water should just cover the amalgam, and the edge of the gold leaf should be allowed to dip a little into the water.)

Fifth.—With potassium amalgam the action is greater.

Sixth.—With the hypothetical hydrogenium or ammonium amalgam, I have found *less action* than the supposedly high electro-positive character of the metal (?) would indicate. This might be accounted for by the porous condition of the amalgam, owing to the gas contained (nitrogen?) and consequently much diffused state of the "metal." I notice this last experiment and reaction merely because it may be valuable in determining whether such gaseous metals exist.

The result here seems to be that we have now for the first time a metallic compound capable of attracting the precious metal gold, when but a short distance intervenes. We can amuse ourselves with the idea that upon this principle a compass may be constructed (a tube charged with the amalgam), which will be to the prospector and gold hunter as the magnetic dip needle is to the searcher after iron ore. Still, there is something inexplicable about it, for this apparent attraction of gold can hardly be magnetic, and it seems to me we must look for explanation to cohesive molecular power.

I have shown that the combination of mercury and iron was long since effected; I have now to claim as a discovery the direct amalgamation of *steel*, even when of the toughest and hardest character. The blade of the best pen-knife is readily amalgamated, and suffers from the contact, while a plate of fine sheet steel, used in the manufacture of superior instruments, is easily coated with mercury and made to resemble a sheet of silver. By magnetising soft steel, reducing a sufficient amount of it to filings, and dissolving the filings in mercury, I have procured a magnetic amalgam, in the presence of which an astatic needle is decidedly bewildered. The horseshoe magnet which has this evening been exhibited brightly coated with and upholding an inverted arch of fluid, dripping mercury, lifts quicksilver, it is true, but quicksilver loaded with an amalgam of magnetised steel; an attraction much stronger than that evinced for iron amalgam.

A glass tube properly charged with the magnetic amalgam exhibits the polarity of the compass needle, and has its extremities attracted and repelled by the poles of the magnet in the same manner that the poles of the compass needle are attracted and repelled. This property of the magnetic amalgam is interesting, as it proves that however minutely divided, the atoms of steel still retain their magnetism, and are still influenced by the directive currents of the earth. I have not yet been able to make a very powerful needle of this kind; but, though my observations are very imperfect, I am able to say that it seems to point a little more truly to the magnetic north, and from its greater inertia to be less subject to irregular changes of variation than the ordinary compass needle. The inertia is to be attributed to the assumption by the magnetised steel of a certain portion of the weight or specific gravity of the mercury. When this amalgam is exposed to the oxidising influence of the atmosphere, it is gradually decomposed, carbon being liberated, and the permanent magnetism vanishing, while iron amalgam remains. This will also finally decompose, pure mercury and ferrous oxide resulting.

Another discovery that I may claim, is the direct amalgamation of *cast-iron*, even of the most brittle and highly carburetted character. This was first effected by means of

a compound amalgam of potassium, sodium, and "ammonium" with water; but I have since found that a simple amalgam of potassium or sodium is generally sufficient to effect the result. The surface of cast-iron may be amalgamated by placing an electro-positive or active amalgam upon it with water or an acid; a true amalgam may be similarly formed with filings.

In the course of the experiments which led to this discovery, it was my fortune to observe phenomena of an extraordinary character. The usual brilliant surface of mercury is produced when cast-iron is treated with the electro-positive amalgam, and the iron is rapidly "cut" or dissolved. The impurities of the iron, with considerable carbon, are released and form a black mud around the button of amalgam. If at this moment, before all the positive metal has been oxidised, the amalgam be removed, washed, and allowed to stand, particles of amorphous carbon will be seen to emerge and float upon its mirror-like surface. Whence comes this carbon; why was it not given up before? Has it been amalgamated; and if so, has it not a metallic character? It has been suggested to me that particles of undissolved iron, containing carbon, have been carried bodily into the amalgam, and afterwards dissolved, releasing their carbon. However, this is but a conjecture; the reaction certainly deserves study.

The mere intimation that carbon, the great protean thing in nature, may, after all, have a metallic origin, is very interesting. Those who believe in the ammonium of Berzelius or the hydrogenium of Graham, need not fear to examine the claims of carbon to a metallic parentage, nor does the existence of such a metal seem so improbable when we remember the electric conductivity of two of the allotropic forms of carbon, gas-coke and plumbago; the first already replacing, in the voltaic batteries of the present day, the electro-negative elements, platinum, copper, &c., while the latter replaces similar electro-negative elements when brushed, in the form of plumbago powder, upon the surface of the mould or plaster-cast which the electroplater desires to coat with copper or other metal.

If metallic carbonium exists, it may be assumed to be an electro-negative metal. It is true that some forms of carbon are highly inflammable, but are they more so than Graham's hydrogenium? Graphite at ordinary temperatures is far from combustible, and when it burns, or when the diamond burns in oxygen gas, wrought-iron will burn also. No one doubts that iron is a metal, yet one of its purest forms is pyrophoric, taking fire and burning on contact with the atmosphere. To associate graphite with sulphur and phosphorus is to place it, a good conductor of electricity, side by side with the very enemies of travelling magnetism. For how many ages was molybdenite undistinguished from graphite, and who is there now that can instantly distinguish the one from the other? It is true that molybdenite is a sulphide of molybdenum, and graphite a pure allotropic form of carbon, but may there not be one more form of carbon? There is no substance in nature more readily recognised as a metal by the unlearned than graphite; to this day it is impossible to take from it the improper title of black-lead. The experiments of Sir Benjamin Brodie with graphite, his discovery of graphic acid and its combination with ammonia (*graphate of ammonia*?) afford another analogy; for molybdenum has its molybdic acid, and what chemist is there that is not familiar with *molybdate of ammonia*? I have found that contact of native graphite with an electro-positive amalgam and water or acid, produces the same reaction and effervescence as when a negative metal occupied the place, but an amalgam did not seem to form.

It would appear that the division of elements into metals and non-metals is as arbitrary as any other absolute division or classification in science; for though the extremes may readily be distinguished,—as gold from fluorine,—the means often approach each other in appearance and in properties.

Besides forming amalgams of steel and cast-iron, I have

succeeded in combining mercury directly with crystalline octahedral iron ore (*magnetite*), and with other ores and some furnace products. The loadstone exhibited, coated with mercury, is from the Adirondack mountains. Red fossiliferous hematite ore from Georgia is also readily amalgamated. Bog-iron has so far resisted mercury, save one specimen from the state of Florida, which appeared to receive it slightly. The *slag*, &c., of the Colorado gold-smelting furnaces may also, by means of the compound amalgam, be coated with mercury. Magnesium may be amalgamated with the aid of zinc-amalgam and chlorhydric acid; much heat is evolved, sufficient indeed to burn the hand if laid upon it. Bisulphide of carbon, treated with the compound amalgam, is decomposed; sulphides of the alkaline metals result, while another portion of sulphur combines with the mercury, forming true vermilion. Carbon separates in form resembling graphite.

The practical applications of these discoveries are numerous. As mercury dissolves iron and its ores, and finally separates the metal from its impurities of silicon, sulphur and phosphorus, it may prove possible to prepare an iron, nearly as pure as that reduced by hydrogen, for medicinal purposes, by distilling the mercury from the amalgam. In accordance with the laws announced, it is evident that plates of amalgamated zinc or iron are superior to plates of copper in effecting the amalgamation of gold, especially if they be treated with proper acid solutions while the stamped ore is being run out over them. Potassium and sodium amalgams are undoubtedly more effective, but can hardly compete with amalgamated zinc-plates in cheapness.

A great philosopher has said that the results of all experiments should be recorded, nothing being worthless that adds to man's knowledge of the properties of matter. It is my hope that the experiments described, and suggestions here thrown out, may not be altogether valueless.

ON THE ZIRCONS OF CEYLON.*

By M. H. COCHRAN, F.C.S.

THE natural silicates of zirconium have of late attracted great attention among chemists by reason of the researches of Messrs. Sorby and Forbes, and on account of the discovery of a supposed new earth associated with zirconia in these minerals.

Many chemists have held the opinion that zirconia was in reality a mixed earth. Svanberg in 1845 announced the discovery of a new element, to which he gave the name norium, in zircons and jargons from Ceylon and Siberia, but as he did not make known the results of any further researches on it, the existence of norium was rendered doubtful.

Mr. Sorby, in 1869, announced the discovery, by means of the micro-spectroscope, of an earth having a totally different absorption spectra from that of any known element, and he succeeded in separating the new earth from zirconia. Mr. David Forbes, at Mr. Sorby's request, made a chemical analysis of Ceylon jargon, and he also succeeded in separating the other earths from zirconia by taking advantage of the insolubility of zirconium chloride in concentrated hydrochloric acid.

Having through the kindness of a friend obtained seven small specimens of jargon and zircon from different localities, I analysed them by the same process which Mr. Sorby adopted.

The finely-powdered mineral was fused thoroughly with a mixture of equal parts of carbonate of soda and carbonate of potash until the silicate was decomposed, a little caustic potash being dropped into the centre of the fused-mass towards the end of the process. This was then treated repeatedly with boiling water, and the silica estimated in the solution in the usual way. The residue

contained all the zirconia; it was tested carefully for silica, but was found completely free from it. It was then once more evaporated to dryness with hydrochloric acid, and the residue treated repeatedly with concentrated hydrochloric acid, which dissolved out a small quantity of sesquioxide of iron, and also the other earth accompanying zirconia, to which Mr. Sorby gives the name jargon. The residue after this treatment was dissolved in water, and the zirconia precipitated by ammonia and weighed, and called A.

To the hydrochloric acid solution ammonia was added, then tartaric acid in excess; a portion of the precipitate at first formed was dissolved, but a quantity remained undissolved; this was washed, dried, ignited, weighed, and marked B; when examined with the micro-spectroscope it was found to have a spectra different from that of any known element.

Ammonia was added to the tartaric acid solution, then sulphide of ammonium, when, after the lapse of some days a precipitate of sulphide of iron was formed; this was collected, converted to sesquioxide of iron, and weighed. After separation of the iron the solution was evaporated to dryness in a platinum basin and ignited strongly for some time, when a residue was left, which appeared to be a third earth; this was marked C. Mr. Forbes's analysis yielded the following numbers:—

Silica	33.61	per cent.
Zirconia A. .. .	46.12	"
" B. .. .	7.64	"
" C. .. .	12.62	"
Sesquioxide of iron ..	0.24	"

100.00

I adopted exactly the same method, but except in one instance everything was precipitated at the stage A, and I could not succeed in obtaining any other earth than zirconia.

The first specimen examined was a jargon from Ceylon; it was almost colourless. 0.9320 grm. yielded on analysis—

Silica	0.316
Zirconia.	0.604

Or, when calculated to per cent—

Silica	33.90
Zirconia.	64.80

It contained no iron.

The second specimen was a pale yellowish hyacinth, also from Ceylon. 0.733 grm. gave—

Silica	0.241, or 32.87	per cent.
Zirconia	0.471, or 64.25	"
Ferric oxide. . . .	0.015, or 2.04	"

The third was a Norwegian zircon, and was of a dark brownish yellow colour. 0.701 grm. gave—

Silica	0.228, or 32.53	per cent.
Zirconia	0.449, or 64.05	"
Ferric oxide. . . .	0.020, or 2.85	"

The fourth specimen was an almost colourless Ceylon jargon. 0.655 grm. gave—

Silica	0.2165, or 33.05	per cent.
Zirconia	0.4370, or 66.71	"

It had only the merest trace of iron.

The fifth was also an almost colourless jargon from Ceylon. 0.503 grm. gave—

Silica	0.1710, or 33.86	per cent.
Zirconia	0.3245, or 64.25	"
Ferric oxide	0.0055, or 1.08	"

The sixth sample was a Norwegian zircon. It had a dark brownish yellow colour, and was almost opaque. 0.5 grm. gave—

Silica	0.1680, or 33.61	per cent.
Zirconia	0.3200, or 64.40	"
Ferric oxide	0.0045, or 0.90	"

* Read before the Glasgow Philosophical Society.

The seventh specimen was a Ceylon jargon, and it was perfectly clear and transparent. 0.488 grm. gave on analysis—

Silica	0.1650, or 33.81 per cent.
Zirconia A	0.2835, or 58.29 "
" B	0.0390, or 8.03 "

It contained a faint trace of iron. The substance marked zirconia B was examined with the micro-spectroscope in the manner described by Mr. Forbes in the *CHEMICAL NEWS*, April 30, 1869; but was entirely unsuccessful in detecting any peculiar absorption-bands. In appearance, and apparently in all its properties, it was exactly the same as the zirconia A. From my examination, therefore, I am inclined to doubt the existence of the so-called jargonia, as I believe the zirconia A and B to be identical.

EXPERIMENTS ON DISINFECTANTS.

A SPECIAL commission was appointed by the Academy of Sciences, at Paris, to study the different means of disinfecting those localities which, during the siege, had been appropriated to persons afflicted with contagious diseases. Its report furnishes some useful guides to the selection and the application of disinfectants.

The report assumes, in the first place, the germ theory of infection.

Placing in the same rank chlorine and the hypochlorites, which effect a veritable disinfection by decomposing the infected gases, and carbolic acid, of more recent application, which prevents or arrests putrid fermentation by destroying the vitality of the principal living agents of the fermentation, the commission compared the effects obtained with those which one might expect from very energetic chemical agents, capable of burning up or otherwise destroying the germs.

The commissioners agreed that the very first place among destructive agents which can attack and destroy infectious germs, should be assigned to hyponitrous acid. Great precaution should be exercised, however, by those employing the very dangerous nitrous vapours. Doors, windows, and the fireplace, should be carefully sealed with gummed paper. The following are the proportions and the quantities of materials to be employed per 30 to 40 cubic metres:—Water, 2 litres; ordinary commercial nitric acid, 1500 grms.; copper turnings or shavings, 300 grms. Earthenware vessels of 8 to 10 litres capacity are employed, one for 30 to 40 cubic metres of space. The exit door is carefully sealed, and the room exposed to the fumes for 48 hours. The person who opens the room must be protected by some means, such as the apparatus of Galibert. Carbolic acid is much more easily applied, is less dangerous and expensive, and seems to offer guarantees of quite equal efficacy, founded on experimental evidence. It is best employed by mixing with sand or sawdust, in the proportion of 1 kilo. of acid and 3 kilos. of the inert material. The mixture is placed in earthen pots, as above, and under the same conditions. Carbolic acid, diluted with 25 to 30 times its weight of water, was found very useful in sprinkling daily the floors and the bedding of sick chambers.

An interesting case is cited, where chlorine and the hypochlorites were powerless to destroy or to transform into inodorous products the gases given off by the bodies at the Paris Morgue during the heat of summer. Only one course remained, and that was to destroy the active sources of the gaseous products. This was accomplished by dissolving a litre of liquid carbolic acid in the reservoir of 1900 litres fresh water, which served to sprinkle the bodies. The suppression of putrid fermentation was complete.

It has been stated, by M. Devergie, that water containing only the 100th part of its weight of carbolic

acid sufficed for the disinfection of the dead-house, during the hottest weather, when it contained from six to seven bodies.

The following is the method of fumigating, with chlorine, the linen, mattresses, and other bedding, according to the latest recommendations of M. Regnaud:—

In a strong canvas bag, of 1 litre capacity, introduce 500 grms. chloride of lime (a mixture of hypochlorite of lime and chloride of calcium, usually at 100°); then sew up the bag. The latter is then placed in an earthen pot containing 1 litre of common hydrochloric acid, sp. gr. 1.15, and 3 litres of water; as soon as the chloride comes in contact with the acid the room is closed, and the goods are left exposed to the chlorine fumes for 24 hours; the room is afterwards ventilated during 48 hours. Ten earthen vessels, as above, disengage 500 litres of chlorine, sufficient to disinfect 20 to 25 mattresses more or less contaminated.—*Le Bulletin du Musée de l'Industrie*.

ON THE PURIFICATION OF SUGAR SOLUTIONS FOR THE OPTICAL SACCHAROMETER.

By P. CASAMAJOR.

In the *American Chemist*, April, 1871, p. 378, is an article by Dr. Stammer, taken from the *Sugar Cane*, on the use of animal charcoal in purifying saccharine solutions for polarimetric analysis. The conclusion which is drawn from the experiments detailed in the article is that animal charcoal absorbs sugar from its solutions, and cannot therefore be used for clarifying saccharine solutions for analysis. This conclusion is certainly interesting in a scientific point of view, but hardly less so in its practical bearings to the sugar manufacturer and refiner. It is a matter of such importance that it cannot be accepted without incontrovertible proof, even if supported by such authority as the name of Dr. Stammer.

After making a great many experiments, I am in a position to state that *animal charcoal does not absorb sugar from its solutions* in the same manner as it absorbs colouring matter, salts of lime, magnesia, iron, &c.

The proof of this I have obtained by eliminating with care every source of error, and repeating the experiments several times with different sugars.

I have proceeded as follows:—In the first place, a solution was used of a sugar light enough to give a liquid fit for the saccharometer with acetate of lead, but without using animal charcoal. This solution was placed in the saccharometer, and the result obtained noted.

This same solution was afterwards filtered over animal charcoal containing 3.8 per cent of water. The saccharometer indicated 2 per cent less of sugar.

Another portion was filtered over animal charcoal containing 8.8 per cent of water. The saccharometer indicated a loss of 5 per cent.

For instance:—16.35 grms. of a light-coloured sugar was dissolved so as to occupy 100 c.c. The solution, after treatment with subacetate of lead, was of a slight yellow colour. The saccharometer indicated 90 per cent. With the portion filtered over animal charcoal containing 3.8 per cent of water, the saccharometer indicated 88 per cent. With the portion filtered over animal charcoal containing 8.8 of water, the saccharometer indicated 85 per cent. These results show that the presence of water in the bone-black will affect the strength of the solution.

The next step was to filter the saccharine solution over perfectly dry animal charcoal. This was obtained by heating animal charcoal for over two hours over a lamp, at 350° F., and *throwing the black, while hot, into a hot and dry bottle*. Immediately afterwards the bottle was hermetically closed.

When this dry black is used no loss of sugar is shown by the saccharometer. There cannot be an error in this,

as the experiment was repeated several times with the same uniform result.

It has been stated that the conclusion of Dr. Stammer is, that animal charcoal absorbs sugar from its solutions. If, however, we examine attentively the table from which this conclusion is drawn, we shall notice that the differences between the percentages of sugar, before and after filtration, are very small, varying from 0.2 of 1 per cent to 0.6 of 1 per cent, except in cases where bone-black was used in large quantities, twice or three times as much as in the greater number of cases. The time of contact of the bone-black with the saccharine solution does not seem to have had any influence on the pretended absorbing power of animal charcoal for sugar. These times of contact vary from 3 hours to 24 hours, but the pretended quantities of sugar absorbed vary independently of these times. The variations when they occur are less than $\frac{1}{4}$ per cent. Nobody who has experience in tests by the optical saccharometer needs to be told that such variations must necessarily take place, even on testing the same solution twice in succession, particularly if it is not perfectly colourless.

In examining the two tables, it seems strange that there is so little difference in the comparative results, as the experiments of Table 1 were made with animal-black that had been heated at 230° F., and those of Table 2 with animal-black that had been heated at 350° F. Bone-black heated at 230° F. does not lose all its water. The water remaining in the black, heated at 230° F., will certainly affect the strength of the solution, and produce an apparent absorption; while bone-black, heated long enough at 350° F., loses all its water, and will not affect the strength of the solution. That the portions mentioned as absorbed are very nearly alike in both tables, except when larger quantities of bone-black are used, shows that the bone-black was not kept perfectly dry.

It is of the utmost importance to use bone-black that has been kept dry in a closed bottle. If the bone-black is allowed to cool in the open air it very quickly absorbs moisture. If used hot it increases the temperature of the solution, and by expansion decreases the percentage shown by the saccharometer. As to putting it in the solution hot and allowing it to cool, if left for several hours, as in some of the tests in these tables, there is great danger of losing sugar by fermentation.

Instead of bone-black I use a process, to obtain colourless saccharine solutions, which has answered with all grades of sugar, and which certainly does not take any additional time, or give any additional trouble. This process is founded on the observation that the facility and perfection of clarifying a solution of sugar by subacetate of lead seems to depend on the quantity of mineral salts contained in the sugar. Thus many very dark inferior sugars, such as Manillas, will give solutions which are easily clarified by subacetate of lead, producing at the same time a dense precipitate. Such sugars give, on incineration, a large quantity of ashes. Other saccharine products, particularly those that have been filtered over bone-black, are not very dark, but subacetate of lead acts on them imperfectly, giving a slight precipitate which stops up the pores of the filters.

Acting on the above observation, I add to saccharine solutions soluble salts capable of giving dense precipitates, with subacetate of lead. I have used at different times chloride of sodium, sulphate of soda, phosphate of soda, and acid phosphate of lime, and have found them all equally effective. Other chlorides, sulphates, phosphates, iodides, &c., will doubtless give the same result.

The soluble salt is added by throwing a pinch of it on the sugar, and dissolving by water afterwards, or by putting in a few drops of a solution of the salt.

The results obtained are very satisfactory, as the solutions are quite, or nearly, colourless, whatever be the kind of sugar treated. A secondary advantage is, that the precipitate is very dense and easy to filter, while some

of the sugars without the addition of the salts filter very slowly.

By a succession of experiments I have ascertained that the addition of the salts mentioned above does not affect the saccharometric percentage of the solution.

In connection with the subject of purifying sugar solutions for the saccharometer, there is an important fact, discovered in this laboratory, by Mr. Henry O. Havemeyer. When in saccharometric tests we are obliged to invert, as in tests of molasses, melados, and very low sugars, the hydrochloric acid used produces such a red colour that the solutions are not fit for the saccharometer unless we are careful not to heat them above 68° C., and to cool them as soon as possible afterwards. The inversion is often imperfect under these circumstances, and the safest way is to invert again until no change is shown by the saccharometer. If this is repeated, the red colour will appear even if the solution is not heated above 68° C., and is cooled quickly.

The important fact mentioned above is, that the addition of a small quantity of protochloride of tin will prevent the formation of the red colour, even if the solution is heated above 70° C., several times, until no variation is shown by the saccharometer.—*American Chemist.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 20th, 1872.

DR. FRANKLAND, F.R.S., President, in the Chair.

THE minutes of the previous meeting having been read, Messrs. Patchett and G. B. Longstaff were formally admitted Fellows of the Society. The donations were then announced, and the names of Messrs. Arthur Willis and Robert Symington Grieve Paton read for the first time: for the third time—Messrs. John Emilius L. Shadwell, M.A., Walter Weldon, Walter Stewart, jun., John Ferguson, M.A., Charles Armbruster, George J. Snelus, and R. Wormell, M.A., B.Sc., who were then ballotted for and duly elected.

THE PRESIDENT said the Fellows might perhaps recollect that, about two years ago, the Society had agreed to make grants not exceeding fifty pounds for the promotion of original research; and he now had to announce that Mr. Hyde Hills had given the sum of ten guineas for the same object, and generously offered to give other ten guineas for each ninety guineas subscribed up to five hundred pounds. He need scarcely ask the Fellows to thank Mr. Hills for his liberality in endeavouring to encourage original research. He would now ask Mr. Deacon to deliver his lecture on his "*Process for the Preparation of Chlorine.*"

The Lecturer said that about two years ago, at Liverpool, he had given an account of his process for the preparation of chlorine from a heated current of hydrochloric acid mixed with air, which since then had been the subject of a great amount of research, with the object of ascertaining how this could be effected continuously, readily, and at the smallest cost. This problem may be resolved into the following:—

1. As to the most suitable active or catalytic substance.
2. Whether the mass or the surface of the substance was the active agent.
3. As to the effect of temperature.
4. As to the best arrangement of the substance.
5. As to the effects produced by variation in the velocity of the current of gas.
6. As to the effect of various proportions of air or oxygen and HCl.

He had observed that the heated mixture of hydrochloric acid and oxygen or air does not yield chlorine, unless it is in the presence of some substance capable of being attacked by the hydrochloric acid, amongst which the copper compounds were eminently active.

Sulphate of copper was fixed upon for economic reasons: and almost all the experiments mentioned in his lecture had been made either with the pure sulphate or with pumice-stone or fragments of clay saturated with it. In experimenting, two clay tubes were generally employed, of different bores, glazed externally, and coated internally with sulphate of copper, placed side by side, and passing through the cork of a glass tube sealed at the other end. The mixed gases, on entering, first traversed the glass tube, and then passed out by the clay tubes. In the more recent experiments this apparatus was placed in a thick massive iron tube, heated externally by a furnace, so as to maintain a uniform temperature. This was measured by the change in electrical resistance of a fine platinum wire, and also by a mechanical pyrometer. The mixed gases were contained in gas-holders worked with strong sulphuric acid, both the amount of hydrochloric acid passed and the amount of chlorine produced being ascertained by passing the gases into a solution of caustic soda.

The Lecturer then explained the numerous diagrams and tabulated results of experiments with which his discourse was illustrated, from which it would appear that there is a certain comparatively small range of temperature, between the critical limits of which the percentage of hydrochloric acid decomposed varies greatly, and that this is not the same for the chloride as for the sulphate of copper, being higher for the latter, although it is the same whether solid sulphate of copper be used or merely pieces of brick saturated with it. This shows that the action is essentially a surface action. It is, however, remarkable that in experiments on a large scale this temperature is invariably lower than in the laboratory experiments, usually 100° or 150° ; also, that when the mixed gases are passed through a series of parallel tubes, an increased velocity in the flow of the gas yields only about one-third the increase of the amount of chlorine produced that an irregular porous surface does under like circumstances.

From the results of all the experiments contained in the tables, the speaker inferred—

1. That with the same mixture of gases, at the same temperature, the amount of hydrochloric acid decomposed by the aid of a molecule of the copper salt, in a given time, depends upon the number of times the molecules of the mixed gases are passed through the sphere of action of the copper salt.
2. That in long tubes of the same diameter the number of opportunities of action in the same time are nearly the same at all velocities.
3. That in long tubes of different diameters the number is the same when the velocities of the currents of gas are in inverse proportion to the square of the diameters.
4. That in porous masses the opportunities of action increase with increased velocities, in nearly direct proportion.
5. That, other conditions remaining the same, the percentage of hydrochloric acid decomposed varies with the square root of the proportionate volume of oxygen to hydrochloric acid.
6. That the CuCl_2 formed bears no definite proportion to the amount of chlorine produced.
7. That as the sphere of action includes molecules not in contact with the copper salt, therefore hydrochloric acid must be decomposed under circumstances where the union of either element with the copper salt is impossible.

The PRESIDENT said he need scarcely ask them further to record their thanks to the lecturer, for the clear and comprehensive account he had given them of his numerous

and interesting experiments on the mutual action of hydrochloric acid and oxygen in the presence of salts of copper. The process for preparing chlorine, at present used, was essentially clumsy and unscientific; the hydrochloric acid given off from the salt cake was first dissolved in water, and then treated with manganic peroxide in order to liberate the chlorine, giving rise, at the same time, to a large amount of waste products, which were thrown into our streams and polluted them. As especially interested in our rivers, he sincerely hoped the process would prove a commercial success.

Dr. WILLIAMSON said he would like to ask a question or two for his own information. He understood that the mixture of air and hydrochloric acid was heated before being passed into the decomposing chamber; was it cooled again before it went into the chambers containing lime for the preparation of chloride of lime, and was the undecomposed hydrochloric acid previously removed by washing?

Dr. DEBUS would like to know whether the sulphate of copper was found to be unaltered after having been exposed to the action of the mixed gases for a considerable time, and also whether, when he used straight tubes with the mixed gases passing through at different velocities, the gas in both instances had attained the same temperature when it came in contact with the sulphate of copper.

Mr. STEVENSON remarked that he had no practical acquaintance with Mr. Deacon's process; but he thought that if the old process continued to be used, we possessed a great advantage in Mr. Weldon's method for revivifying the manganese, so that, in this revolutionary period of the manufacture, we had the benefit of both processes.

Dr. VOELCKER said the lecturer had made an allusion to the action of chromium on the mixed gases in the early part of his lecture; would he, perhaps, kindly explain what was its especial peculiarity?

Dr. GLADSTONE observed that many interesting points started up in one's mind in connection with this subject, and he should like to know more fully why the lecturer believed the sphere of action to include molecules not in contact, and that the decomposition was not due to direct chemical action. It appeared to him that it was unnecessary to suppose the cause to be the mechanical striking of the molecules of the gas against the sulphate of copper surface, in their passage through the apparatus, and therefore depending on the flow; for it must be remembered that, when a gas was mechanically in a state of rest, the molecules composing the gas are in a state of motion, and that when we heat that gas this rate of motion of the molecules amongst themselves varies, although the gas is still mechanically at rest.

Mr. DEACON replied that it was one thing to express clearly what one had carefully thought over, and another to answer, off-hand, questions that embraced a wide field of enquiry; moreover, he had come there to speak simply on the scientific aspect of his subject, and he thought it would save the time of the Fellows present, and avoid going over old ground, if they would permit him to put aside all technical questions, and reply only to those which had a scientific interest.

In the first place, there is a definite range of temperature where chlorine is freely formed, but no chloride of copper; although at a higher temperature, the sulphate of copper is partly converted into chloride. This only applies to pure sulphate of copper, which, even after the action had been continued for six months, contained but mere traces of chlorine. In the presence of clay, however, the sulphate of copper is decomposed, and chloride formed, probably owing to its containing some base which combines with the sulphuric acid.

In the case where the exterior glass tube contained two clay tubes of different diameters, the gas coming in contact with the copper salt certainly had the same temperature, although moving with different velocities.

With regard to his allusion to chromium, he had ex-

pected—from the well-known oxidising power of chromic acid—that it would have been very active, but, on the contrary, he had found that it was reduced to oxide of chromium, which is one of the most inactive substances.

With respect to the theory he had laid before them, without vouching for its correctness, he could say that it was the only way he knew of accounting for the results he had obtained.

After a vote of thanks to the lecturer, the meeting adjourned over the recess.

CORRESPONDENCE.

MANUFACTURE OF SULPHATE OF AMMONIA— PROPOSED ASSOCIATION OF MANUFACTURING CHEMISTS.

To the Editor of the Chemical News.

SIR,—Can some reader of the CHEMICAL NEWS tell me whether gas-works ammoniacal liquor is distilled anywhere in England at the present day on the continuous and economical principle of Coffey's Still? If so, a brief description of the apparatus and results obtained in working would, I am sure, interest the large number of your readers connected with the manufacture of sulphate of ammonia,—certainly the great majority of whom work on the more wasteful and costly plan of boiling off in charges by fire or steam, or of evaporation to crystallising-point after saturating with acid. I know a works where plant is just about to be erected for thus evaporating 90,000 gallons per week, at an estimated weekly expenditure of 50 tons of coal!

I have been very much struck for some time back with the extraordinary isolation with which we English chemical manufacturers surround ourselves. I have repeatedly discovered gentlemen within a few miles of the works with which I am connected, blundering away at problems which have been settled here years before, and the solution of which we should have been most happy to show them, had they had the courage to ask our experience in the matter. Similarly, I confess to have found ourselves on the wrong side of methods and plans which others had elaborated, which they had no special interest in keeping secret, and the earlier adoption of which by ourselves might have saved years of time and hundreds of pounds of expense. I am persuaded that the secretiveness and isolation from our neighbours which, as manufacturers, so many of us deem it necessary to keep up, loses us vastly more than we would gain by a frequent interchange of ideas and experiences.

Let none of your readers imagine me a disciple of Mr. Macfie. I am, and always have been, a warm advocate of a Patent Law; and while I believe that there are numberless auxiliary methods and plans of a kind which manufacturers never dream of patenting (which they would be glad to exchange and reciprocate with others), I consider that nothing would so much promote the introduction of valuable patents as the periodically bringing together, for mutual interests, of the great body of manufacturing chemists.

Let it not be forgotten that the large-souled recognition of this truth by the iron-masters, in the formation of their new Iron and Steel Institute, has led directly to the adoption of the invaluable Danks furnace.

I submit to your readers that the time has come for an Association of Manufacturing Chemists, holding an annual gathering, at which the manufacture of at least the great staple, sulphuric acid, might be discussed, scientific and technical papers of general interest read, and such questions considered as the transfer of chemical works from the supervision and control of illiterate Local

Board inspectors to that of the intelligent and scientific staff administering the Alkali A.C. Everybody knows that the two great results of that A.C. have been, (1) to deliver alkali-makers from the miseries and heart-burnings of nuisance-making; (2) to compel them to make money by condensing a corrosive acid. I ask whether a similar result in other branches of manufacturing chemistry would not be infinitely preferable to the state of siege (in fact, in some districts, absolute prohibition of manufacture) now kept up by Local Boards. Other matters of daily-increasing importance, such as the rapid growth and scientific treatment of chemical manufacturing on the Continent, might be discussed with immense advantage.

Trusting some of your readers will take up other phases of the question, and that the matter will not be allowed to drop till a strong national association has been formed,
—I am, &c.,
FRANK.

June 22, 1872.

THE ATOMIC HYPOTHESIS.

To the Editor of the Chemical News.

SIR,—After the very positive assertions made by Mr. Atkinson (without accompanying evidence) in CHEMICAL NEWS, vol. xxv., p. 273, it may appear somewhat rash to continue the discussion; but with your permission I would offer a few points for consideration.

According to J. S. Mill "an hypothesis is any supposition which we may make (either without actual evidence, or on evidence avowedly insufficient) in order to endeavour to deduce from it conclusions in accordance with facts which are known to be real." And he goes on to say that an hypothesis for verification requires it to be shown, in the first place, that from it the known facts may be deduced; and, in the second place, that *they can be deduced from no other*. Now, even if the first requisite be admitted in the case under discussion, I am not aware the second has been attempted, so it would seem that the atomic hypothesis is still unverified.

Mr. Atkinson's argument, that the law of multiple proportions cannot exist apart from the atomic hypothesis because it is not in exact accord with experimental results, appears to me to be equally opposed to the hypothesis, unless the latter can be supported by *extra chemical evidence*; for, as far as chemistry is concerned, it depends on precisely the same kind of experimental results, and is in no closer accord with them than is the law of multiple proportions. Indeed, I might have said on *supernatural* evidence, for all natural laws have experimental bases.

Turning to the historical side of the subject, I think it may be shown that Dalton discovered the law of multiple proportions before he devised the atomic hypothesis. In his earliest chemical memoir, in 1802, he says "the elements of oxygen may combine with a certain portion of nitrous gas, or with twice that portion, but with no intermediate quantity." His first table of atomic weights was read in 1803, a year later, and is most clearly based upon experiment. His biographer, Dr. Henry, is led to conclude that "the discovery of the law of multiple proportions was, in the order of mental operations, the immediate antecedent of the atomic theory of chemical combination." Richter, between 1789 and 1802, constructed a table of reciprocal proportions, and Dalton is said to have acknowledged that this suggested to him the speculations which led to the atomic hypothesis. This has been denied; but, in any case, Richter's law preceded the hypothesis.

It is instructive to note the views of two such thinkers as Davy and Faraday on this question. In Thompson's "History of Chemistry," it is stated that Thompson first, and then Thompson and Wollaston together, tried in vain to induce Davy to accept the hypothesis, but that Davies Gilbert afterwards succeeded. Yet in 1811 Davy writes:—"It is not on any speculation upon the ultimate

particles of matter that the true theory of definite proportions must ultimately rest;" and in his works he refused to employ the term "atom," preferring "proportion."

In 1853, Faraday writes:—"As to the little solid particles which are by some supposed to exist independent of the forces of matter . . . as I cannot form any idea of them apart from the forces, so I neither admit nor deny them. They do not afford me the least help in my endeavour to form an idea of a particle of matter. On the contrary, they greatly embarrass me." "The notion of a solid nucleus without properties . . . becomes to me hypothetical, and what is more, a very clumsy hypothesis."

In the same year, Liebig, while supporting the atomic hypothesis, said:—"Dalton's atomic theory was a product of the age, and sprang forth in his mind, as a consequence of the discovery of chemical proportions or equivalents."

The rapid advance of chemistry where the atomic hypothesis is accepted would furnish a valid argument in its favour, but that, as I believe it is due not to the hypothesis at all, but to the application of the several laws of combination and the use of symbols, all which are susceptible of proof quite independently of the hypothesis.

I should like to say a little about the question of isomerism, but, in view of the length of this letter, will content myself with remarking that it appears to me that the explanation offered by the atomic hypothesis involves three assumptions—first, that matter is ultimately composed of atoms; second, that in isomeric bodies the constituent atoms are differently arranged; and third, that this difference of arrangement is the cause of the observed difference of physical properties. As far as I know, saying nothing of the first of these assumptions, no evidence whatever has been brought forward in support of the second and third. The so-called explanation is about as real as that which accounts for the action of manganese dioxide in reducing the temperature of decomposition of potassium chlorate, by saying that it is catalytic.

Apologising for so great a trespass on your space, I am, &c.,

WILLIAM THORP, JUN.

June 19, 1872.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgement. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 3, 1872.

This number opens with a short account of the mission which M. de Quatrefages and E. Becquerel have performed as representatives of the Academy, at the centenary celebration of the Royal Belgian Academy of Sciences, recently held at Brussels. It appears that the French delegates are highly pleased with their reception, and intend to give a more detailed account of the proceedings at which they have assisted.

The following papers relating more particularly to chemistry are published in this number:—

Formation of Acetylen by Means of Electric Discharges not attended with Sparks (Décharge Obscure).—Dr. Berthelot.—After first referring to the modes of formation of acetylen in general, the author states that he also obtained this body by applying Houzeau's apparatus for making ozone, passing the electric current through hydrogen saturated with vapours of hydrocarbons; but the quantity of acetylen thus formed is very small, and the author ascribes this to the fact that the electric discharge attended with sparks has a far higher temperature than the dark (non-luminous) discharge, and

that, while acetylen is not decomposed by a high temperature, ozone cannot be formed under the latter condition.

Conversion of Ethyl-Naphthalin into Acenaphthen.—Drs. Berthelot and Bardsy.—Ethyl-naphthalin is a complex hydrocarbon, discovered by Drs. Fittig and Remsen, by means of the reaction of bromated naphthalin, hydriodic ether, and sodium. Ethyl-naphthalin, $C_{14}H_{14}C_{10}H_8$, differs from acenaphthen in having two equivalents more of hydrogen, the formula of acenaphthen being $C_{14}H_{12}C_{10}H_8$. This last-named body was first discovered by the authors, having been prepared by causing ethylen or acetylen to react at red heat upon naphthalin; acenaphthen occurs ready formed in coal-tar. The methods of conversion of ethyl-naphthalin into acenaphthen are described by the authors at length: one of these methods consists in passing ethyl-naphthalin through a red-hot tube, this decomposition being elucidated by the formula—

Another method is by the wet way—treatment with bromine and alcoholic potassa solution, at a higher temperature: this reaction—which, however, yields only a very small quantity of acenaphthen—is elucidated by the following formula:—

Ethyl-benzine has been by the authors converted, by the last-mentioned method, into styrolen.

Although not strictly belonging to chemical subjects, we quote the titles of the two following memoirs:—

Observations on Chlorosis and Anæmia as affecting Men and Women, a Communication made in consequence of Bousingault's Memoir on the Iron contained in Blood and Food.—Dr. Bouillaud.—A very important physiologico-pathological paper.

Note on the Distribution of the Water of the River Rhone, at Nîmes.—A. Dumont.—This memoir contains a condensed description of an ingenious mode of supplying Nîmes with water from the River Rhone, which water is naturally filtered (*filtration naturelle*), while passing through the subterranean aqueduct, the largest now known to exist. This city, it should be remembered, was in ancient times copiously and magnificently provided with pure water by the aqueduct—now partly in ruins—known as the *Pont du Gard*, and destroyed by the Vandals.

La Revue Scientifique de la France et de l'Etranger,
June 15, 1872.

This number contains no papers relating to chemistry.

On Animal Heat.—Dr. C. Bernard.—These excellent lectures are continued, and deserve attention. This portion, which is illustrated with woodcuts, treats on the influence of the nervous system, and more particularly the sympathetic system upon circulation, and collaterally upon animal heat.

Bulletin de la Société Chimique de Paris, Vol. 17, No. 4,
February 15, 1872.

From the *procès-verbaux* of the meeting of this Society referred to in this number, we quote the following particulars:—

Chlorides of Sulphur.—M. Maumené.—The author states that he has obtained by the action of chlorine upon sulphide of carbon, two peculiar chlorides, viz., (1), $CSCl_2$, boiling at 47° ; (2), $CSCl_4$, boiling at 70° . Dr. Guignet observes that sulphide of carbon is very readily acted upon by chlorine, even when the latter is left in contact with the former in the state of solution, as chloride of carbon and chloride of sulphur are then formed. When vapours of sulphide of carbon and chlorine are passed through a red-hot tube, tetrachloride of carbon is abundantly formed; the same obtains when sulphide of carbon is treated with perchloride of antimony, in which case a smaller quantity of by-products are obtained.

The following original memoirs are contained in this number:—

Temperature at which the Spontaneous Crystallisation of a Supersaturated Solution of Sulphate of Soda takes place.—L. C. de Coppet.—We regret that the great length of this memoir, and the necessity of reproducing several tabulated formulæ essentially required for the proper understanding of the subject, render it unsuitable for useful abstraction, notwithstanding its high intrinsic merits.

On Sexbasic Saccharate of Lime.—H. Déon.—When tribasic saccharate of lime is treated with alcohol the sexbasic saccharate is obtained by elimination of one-half of the sugar, exactly in the same way as by treatment of the monobasic saccharate with alcohol yields the bibasic saccharate; while the monobasic and tribasic saccharates contain water, the bibasic and sexbasic saccharates contain none. The reactions are thus analogous, and may be expressed by the following formulæ:— $C_{12}H_{11}O_{11}CaO$, derived from—

derived from $2(C_{12}H_{11}O_{11}CaO + HO)$; when sexbasic saccharate is combined with two equivalents of sugar, bibasic saccharate is obtained,—and when two equivalents of sugar are added to tribasic saccharate, monobasic saccharate is formed.

Black Colouring Matter contained in Native Bitumen.—MM. Le Bel and A. Muntz.—The authors have extracted from bitumen (native, as well as that obtained from tar) a black-coloured substance, insoluble in alcohol and ether, soluble in sulphide of carbon and chloroform, and fusing—without volatilising—at between 130° and 145° . This substance, which possesses very great colouring power,

has been called asphaltene, and was found to consist chiefly of carbon and hydrogen. From an Egyptian bitumen the authors also obtained a similar body, but this was found to contain more oxygen, and, moreover, a notably large proportion of ash.

No. 5, March 1, 1872.

This number contains the following original papers and memoirs:—

Acetic Ethers of Dulcitol and Dulcitan.—G. Bouchardat.—The following compounds are described:—Diacetic dulcitol—

a solid crystalline body, soluble in water, nearly insoluble in alcohol and in ether, fuses at 175°, is partly decomposed by boiling water, also by alkaline solutions; hexacetic dulcitol, $C_{12}H_{22}(C_2H_4O)_6$, also a solid crystalline compound, fusing at 171°, sublimable at 250° in an atmosphere of carbonic acid, nearly insoluble in cold water and in cold alcohol and ether,—hot water and weak alkaline solutions decompose this compound; pentaceto-monochlorhydril-dulcitol—

is a solid crystalline compound, almost insoluble in all neutral solvents, while at the boiling-point of the same the compound is decomposed into pentacetic dulcitol and hydrochloric acid,—boiling acetic acid converts it into hexacetic dulcitol; pentacetic dulcitol—

fuses at 165°, sublimes at 250°; diacetic dulcitan—

is an amorphous, viscous, bitter-tasted substance, soluble in cold water, alcohol, and ether, and converted into tetracetic dulcitan, at 180°, by anhydrous acetic acid; tetracetic dulcitan—

is an amorphous resin-like substance, insoluble in cold water, very soluble in cold alcohol and ether.

Conversion of Aceton into Hydruret of Hexylen.—G. Bouchardat.—This paper treats on a compound produced by the action of nascent hydrogen upon aceton, viz., $2C_6H_5O_2 + H_2 = C_{12}H_{18}O_4$, which, according to the author, may be considered as dipropyl or hydruret of hexylen. To prove this a series of experiments have been made, the result of which confirms the author's opinion.

No. 6, March 15, 1872.

This number only contains the following original paper—

Solubility of Oxides in Alkalies.—M. Prud'Homme.—The main gist of this short notice is, that the addition of a small quantity of a salt of copper to a liquid containing a precipitate of sesquioxide of chromium (produced by ammonia in excess) re-dissolves that precipitate, which, however, reappears on boiling the liquid; inversely, oxide of copper is dissolved in potassa, in the presence of a salt of chromium, but at a higher temperature (above 100°) the oxide of copper is precipitated.

No. 7, April 1, 1872.

This number contains the following original papers and essays:—Industrial Manufacture of Chlorine.—F. de Lalande and M. Prud'Homme.—Reserved for full translation.

On some Facts of Incomplete Oxidation as observed to take place in the Human Organism.—G. Daremberg.—The author relates, at length, a series of chemico-pathological researches, from which it appears that, in heart and lung diseases, the urea secretion decreases and that of uric acid increases.

On Ammoniacal Platinum Bases.—P. F. Cleve.—The fourth instalment of a lengthy monograph on this subject, this part being divided into the following sections:—Derivatives of platosemidiamine which contain aniline; derivatives of platosemine which contain aniline; derivatives of platosemidiamine which contain ethylamine; derivatives of platosemine which contain ethylamine.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 10, 1872.

This number contains the following original papers and memoirs:—

Non-Existence of Parathionic Acid.—C. Scheibler.—Referring to Erlenmeyer's researches, lately published on this subject, the author has proved the non-existence of this acid (first discovered and described by Gerhardt, in his *Traité de Chimie Organique*, as a body isomeric with ethyl-sulphuric acid) as far back as the year 1862, at which period the author made a communication on the subject at the meeting of the German philosophers and savants, held at Karlsbad, which communication was duly published in the *Tageblatt* of that meeting, pp. 66 and 80.

New Method of Synthesis of Diphenylketon.—M. Kollarits and V. Merz.—Benzoic acid and benzol were introduced, with anhydrous phosphoric acid, into a strong glass tube, which, having been sealed, was heated for a considerable time up to 180° to 200°. After treating the contents of the tube first with ligroine then with caustic potassa-solution, and afterwards submitting the oily fluid to fractional distillation, the authors obtained diphenylketon as a beautifully-crystalline body, fusing at about 49° and boiling at 300°, yielding on elementary analysis results which led to the formula $C_{15}H_{10}O$ diphenylketon. In the presence of anhydrous phosphoric acid, benzol behaves with benzoic acid as an alcohol does with acids, the benzol hydrogen being eliminated as an alcoholic hydrogen;

the authors take, for this method of preparation of diphenylketon, 5 parts of benzoic acid, 6 of benzol, and 8 of anhydrous phosphoric acid, and heat for about five hours.

Researches on the Glycerine Derivatives.—L. Henry.—This exhaustive memoir, treating on the glycid and propargyl compounds, is elucidated by lengthy and complex formulæ.

Perchlorphenol.—V. Merz and W. Weith.—After first referring to the researches of Erdmann, Laurent, Schützenberger, and others on this subject, the authors describe the method of preparation of per- or penta-chlorphenol by treating with chlorine gas a mixture of 3 parts of phenol and 1 of chloride of antimony placed in a suitably-constructed vessel in a water-bath. After a somewhat tedious process of purification, there is obtained perchlorphenol, a solid crystalline substance soluble in ether and alcohol. These solutions exhibit acid reaction to test-paper. Perchlorphenol fuses at from 186° to 187°, and may be sublimed; potassium-perchlorphenylate, C_6Cl_5OK , obtained by treating perchlorphenol with potassa, is soluble in a mixture of ether and alcohol, crystalline, contains 12.87 per cent of potassium. The authors further describe at length the action of nascent hydrogen, of concentrated nitric acid (which, at the ordinary temperature, converts perchlorphenol into perchlorchinon), of chloride of phosphorus upon perchlorphenol. When the above-mentioned potassium salt is submitted to a high temperature, there is formed perchlorphenyl oxide, C_6Cl_5O , molecular formula—

Its mode of formation from potassium-perchlorphenylate is elucidated by the following formula— $C_6Cl_5OK = KCl + C_6Cl_5O$.

Physical Feasibility (Physikalische Möglichkeit) of the most Recent Hypothesis Set Forth by Kekulé Concerning Benzol.—A. Michaelis. This algebraic-physical essay is, notwithstanding its scientific value, not well suited for abstraction.

Monochlorcrotonic Acid Obtained from Croton-chloral.—C. Sarnow.—This monograph is divided into the following sections:—introduction, treating on the acid ($C_4H_5O_2$) obtained by Geuther from monochlor-tetracylic acid; monochlor-crotonic acid and its salts; monochlor-crotonitrile (C_4H_5ClN); monochlorbrom-butyric acid ($C_4H_5ClBrO_2$) and its salts.

On Some Pigments Derived from the Aromatic Azodiamines.—Dr. A. W. Hofmann and A. Geyer.—The first instalment of a lengthy monograph on this subject, this part treating on azodiphenyl blue.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, April 18, 1872.

Description of a Newly-invented Press for Extracting the Juice from Beet-root Pulp.—M. Camponnois.—This contrivance, illustrated by a woodcut, appears to be in every respect superior to the machinery now in use for this purpose.

Atmismometer.—M. Piche.—The description of an instrument invented by the author, and destined to measure the degree of evaporation and its rapidity; it is therefore a complement to the psychrometer.

Glass-made Plummer-Blocks and Axle-Bearings.—MM. De Camus and Haret.—From what is stated here, it would appear that glass is successfully substituted by the authors for bronze, in the pieces of machinery just mentioned. The use of glass for the purpose alluded to seems to be attended with many advantages, and among these that of requiring less labour in making the articles, and greatly decreased consumption of lubricating material.

Les Mondes, June 13, 1872.

Inspector-General of Meteorological Stations in France.—Dr. Charles Sainte-Claire Deville has been appointed to the post just named.

Petites Annales de Chimie.—Dr. Maumené.—Under this title the author continues to expound his views on theoretical chemistry. This memoir is illustrated by a series of formulæ.

Laws relating to the Solubility of Salts and the Elementary Gases in Water.—D. Tommasi.—The author states that for salts having the same chemical formula (sulphates, bromides), the co-efficients of solubility in water are in direct relation to their specific heat. This is illustrated by a series of examples exhibited in tabulated forms. As regards the elementary gases (chlorine, oxygen, &c.), their solubility in water is in the inverse ratio of their specific heat.

June 20, 1872.

Catalogue of Raw Materials.—M. Bernardin.—The author has published, first, a descriptive catalogue of all the oils, next, of all the textile fibres, and recently, of all tanning materials, and is now occupied with a similar work on woods. According to the brief account here given of these works, they are highly valuable to industry and commerce.

Cause of the Spectrum Rays.—A. Cauchy.—This paper contains an account of the cause of the spectrum rays, as explained by the undulation theory of light.

Modification of the Electric Machine.—L. Brunelli.—This paper treats on the improvements made by A. Kundt in the instrument alluded to.

A Lightning-Conductor Destroyed by Lightning.—M. Désiré. —An account of an occurrence in Belgium; a lightning-rod was completely demolished, and great damage done to the building it was intended to protect.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 234, June, 1872.

This number contains no original papers relating to chemistry.

NOTES AND QUERIES.

Iodine.—(Reply to J. S.)—You will have to make a full analysis of the material. Consult Fresenius, or, for volumetrical methods, the latest edition of Mr. Sutton's excellent work lately advertised in the *CHEMICAL NEWS*.—A.

Salts of Chromium.—(Reply to "Chromium").—As laboratory specimens, yes; commercially it would be difficult, not however impossible, but would add to the cost of the material; practically the commercial products are pure enough for use.—X.

TO CORRESPONDENTS.

* Vol. XXIV. of the *CHEMICAL NEWS*, containing a copious index, is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. If sent to our office, or, if accompanied by a cloth case, for 7s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxv. commenced on January 5th, and will be complete in twenty-six numbers. **READING CASES**, price 1s. 6d. each, post free, may also be obtained at the Office.

P. M.—(1). Study Miller's work on Chemistry, published by Longmans and Co. (2). It entirely depends upon the size of the works, the knowledge and skill required, &c.

G. W.—Consult Watts's "Dictionary of Chemistry" and Fresenius's "Quantitative Analysis."

Now ready, Vol. I., New Series, cloth 8vo., price 21s., Illustrated with Chromolithograph, 4 Page Plates, and 81 Woodcuts.

The Quarterly Journal of Science, and Annals of Mining, Metallurgy, Engineering, Industrial Arts, Manufactures, and Technology. Edited by WILLIAM CROOKES, F.R.S., &c.

London: Offices of the Quarterly Journal of Science, 3, Horse-Shoe Court, Ludgate Hill, E.C.

Now ready, 4th thousand, price 1s.

Psychic Force and Modern Spiritualism: a Reply to the "Quarterly Review" and other critics. By WILLIAM CROOKES, F.R.S., &c. To which is added Correspondence upon Dr. Carpenter's asserted refutation of the author's experimental proof of the existence of a hitherto-undetected force.

"The correspondence impresses us—less from anything it says, than from what it avoids saying—with the notion that the Fellows of the Royal Society are so susceptible to a possible charge of engaging in investigations that may have ridicule attached to them, that they do not give Mr. Crookes fair play. . . . Mr. Crookes certainly comes out of this correspondence better than his correspondents."—*Spectator*.

London: Longmans, Green, and Co., Paternoster Row.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIÈRE AND CO., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of **PRACTICAL CHEMISTRY**, particularly in its application to **MEDICINE, AGRICULTURE, and COMMERCE.**

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake **ANALYSES** of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

North London School of Chemistry, Pharmacy, &c.—For instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years *Principal Instructor* in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a *Botanic garden*. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871—1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual **EXCURSIONS** for the **STUDY of PRACTICAL BOTANY** will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

AMSTERDAM EXHIBITION, 1869.

The **GRAND DIPLOMA of HONOUR**, being the First Prize, and **SUPERIOR** to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2½d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar. Sold by all Italian Warehousemen, Grocers, Chemists, and Ship Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT of MEAT COMPANY (LIMITED), 43, MARK LANE, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with *boiling-hot water* will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British French, Prussian, Russian and other Governments.

INDEX.

A B C PROCESS for stilling sewage, 217
Abietene, a new hydrocarbon, 166
Acenaphthen, conversion of ethylnaphthalin into, 310
Acetic ether, successive action of sodium and iodide of ethyl on, 208, 219, 223, 235
 ethers of dulcite, 142, 311
Acetone, conversion of into hydride of hexylen, 178, 311
Acetylen, formation of by means of electric discharges not attended with sparks, 310
Aciamides, action of pentachloride of phosphorus on, 155
Acid, monochlorocrotic, obtained from croton-chloral, 311
 parathionic, non-existence of, 311
Adams, J., jun., double chloride of nickel and ammonium, 187
Adger, J. B., analysis of an anomalous variety of stannite from Corawall, 259
Aeby, C., water contained in wells situated in towns and populous places, 107
Aërial navigation, 23, 119
Æsculin, constitution of, 46
Afinity, phenomenon of, 179
Agaricus oreades, chemistry and physiology of, 153
Agriculture, services rendered by chemistry to, 167
Agricultural instruction, 179
Agular, A. A. de, on nitronaphthalin, 286
Air, atmospheric, 167, 180
Albrecht, M., methyl-mercaptan-trisulphonic acid, methyl-mercaptan-disulphonic acid, and methyl-alcohol-trisulphonic acid, 202
Albumen, decomposition of by permanganate of potassa, 46
 new derivatives of, 164
Atcherley, R. J., estimation of nitrogen in nitrates, 200
Alcohol to aid in detecting adulteration of wax with tallow, 167
 elimination of, 61
 preparation of absolute, 22
Alcohols, anisic and methyl-salicylic, 300
 fatty, formation from their initial constituent molecules, 46
 in chemistry, 83
 tertiary, oxidation of, 107
Alcoholic ferments, morphological studies on, 118
Liquide, ozone for maturing and mellowing, 118
Aldehyde alcohol, 299
 butylen glycol, a new product of the condensation of, 95
 condensation products of, 215, 227
Aldehydes, combinations of with the phenols, 58, 191
Alglave, E., organic chemistry, 287
Alizarine and anthracene, secondary colouring matter in preparation of, 284
Alkalimeter, new, 68

Alkalies, solubility of oxides in, 311
Alkaline bisulphites, action on some of the diazo-compounds, 106
Alkaloids of the cinchona trees, 22
 conversion of phenol into, 81
 opium, 182, 185, 193, 285
Allen, A. H., metastannic acid and estimation and detection of tin, 128, 170
 solubility of gold and stability of auric nitrate and sulphate, 85
Allyl-sulphonic acid and its salts, 202
Almonds, essential oil of, detection of nitrobenzol in, 167
Alees, Barbadoes, crystalline principle of, 66
 new acid from, 179
 products from, 229
Alum, chemical investigation of a complex, from the thermomineral water of the Solfatara, 70
 in bread, logwood test for, 207, 230
Alumina oxides in the manufacture of superphosphate, 235
 phosphoric acid, ferric oxide, lime, and magnesia, separation of, 277
Amagat, M., expansion of moist gases, 285
Amato, D., synthesis of condensed hydrocarbons, 167
 dicyanacetic acid, 263
Amber, fluorescent, 131
Amblygonite, analysis of, 45
 from Montebias, 131
Amides, action of fluid phœgen on, 119
Amido acids, new, 46
 compounds, action of on chloral, 190
Amido-benzo-sulpho acid, 35, 94
Amido-sulpho-benzide acid, 118
Amido-camphoric acid, 46
Amines, aromatic, substitution of, 34
Ammonia, assimilation of by yeast, 275
 manufacture of sulphate of, 309
 nitrate of, formation of in respiration, 118
 prepared from the nitrogen of the air, 143
 use of in revivification of bone-black in sugar refineries, 34
Ammoniacal platinum bases, 47, 286, 311
 salts, estimation of, 214
Ammonium and nickel, double chloride of, 187
 sulphide and chloral hydrate, reaction of, 37
Amorphous silica as a mordant for dyes and pigments, 215
Ampelopsis hederacea, chemical constituents of the leaves of, 202
Amyl derivatives, piperidine from, 190
Analysis of water, 129, 140, 273

Anhydrides and chlorides, action of phosphoric chloride on, 106
Aniline, artificial production of, 21 blue, sulpho-acids of, 287
 colouring matter from, 215
 commercial, decomposition of, 191
 dyes, estimating the value of, 34
 freezing-point of, 155
 red, formation of, 106
Animal heat, 310
Anisic and methyl-salicylic alcohols, 300
Anthracen, 180, 275
 and alizarine, secondary colouring matter in preparation of, 284
 derivatives of, 21, 94
 preparation of, 163
Anthrachinon, nitrogen compounds of, 22
 oxidation of by means of hydrate of potassa, 202
Anthracite, to determine carbon in, 271
Anthraquinon, an isomer of, 286
Anthropology, lecture on, 83, 95
Anti-combustion substances, 202
Antimony, docimastic separation of from bismuth, 85, 100
Antimonic acid, composition of hydrate of, 106
"Antiseptic System : a Treatise on Carbolic Acid and its Compounds" (review), 31
Arboriculture, importance of delicivty, 143
Arsenic, docimastic separation of bismuth from, 85, 100
Arsenical poisoning by wall coverings, 141
Artesian wells, dynamite for boring, 107
Asbestos cloth, 59, 83
Ascher, M., threefold substituted benzols, 46
Asparagine in vetches, 118
Asphalte, compressed, pavement made with at Munich, 70
Assay of gold and silver, 37, 51
 of iron ores, 160
Atelier de Silex Préhistoriques, 276
Atkinson, E., "Natural Philosophy for General Readers and Young Persons" (review), 250
R. W., atomic theory, 249, 273
Atmometer, 311
Atmosphere, presence of vesicles of vapour in, 70
 researches on, 251
Atomic hypothesis, 309
 relations between and the condensed symbolic expression of chemical facts and changes known as dissected formulae, 67, 74
 theory, 118, 249, 251, 266, 273
 weight and specific heat, relation between, 39
 of the chemical elements, 63
 weights, 352
Audouin, M., anthracen, 180
Aurin, 35
Aurora borealis, 119, 145
Azo-compounds of rosocin, 263

Azodiamines, aromatic, pigments derived from, 311
BAEYER, A., aldehydes with phenols, 58, 191

No. 658.—FRIDAY, JULY 5, 1872.

THE PROPOSED ASSOCIATION OF MANUFACTURING CHEMISTS.

It has been suggested by a correspondent in our issue of last week that considerable advantages would result to manufacturing chemists and their managers by the formation of an association devoted to the interests, commercial and technical, of chemical industry. It is our purpose to submit to our readers a more prominent notice of this suggestion, according as it does with views long held by us.

There are but few industries that have no representative body, and amongst these few ranks manufacturing chemistry. That manufacturing chemists should not be represented by any general association is not so strange as, on first consideration, it may appear; for the utilisation of by-products, by which manufacturing chemistry has attained much of its important commercial standing is a recent event in the chronology of chemical industry. But now, as our correspondent writes, "the time has come for an Association of Manufacturing Chemists, holding an annual gathering, at which the manufacture of at least the great staple, sulphuric acid, might be discussed, scientific and technical papers of general interest read, and problems of various kinds considered." The benefits that would accrue to the manufacturers themselves from membership of such an association it is difficult, from the variety, to enumerate. In the first place, the expense of many useless experiments would be saved by reference (in after-time) to the collected papers of the association, and especially by personal reference during a meeting of the chief or sub-associations. For we anticipate that the necessary result of an annual meeting would be the formation of auxiliary local associations in the several centres of chemical industry. Not only would the manufacture of sulphuric acid, chlorinated products, ammonia, economic heating, construction of plant, &c., receive their due amount of attention—more than now, because inventors or introducers would be brought into closer contact with manufacturers on the large and small scales, receiving notes of failure or hints of improvement where their processes were employed—but data upon which might be founded remunerative utilisations of by-products would probably be evolved. At present, save in rare instances, there is little communication on points of detail between manufacturers, yet no one better than the manufacturer knows the essential and expensive character of such detail, upon which the

successful issue of his process not unfrequently depends. As we have said, an Association of Manufacturing Chemists would form a medium for the interchange of this detail. While, as our correspondent observes, there may be numerous methods of a kind which manufacturers never dream of patenting, and which they would be glad to exchange and reciprocate with others.

It may be advanced that the preclusive character of certain "trade secrets" would form an insuperable obstacle to the smooth working of the association. We do not think so. The day for the preclusion of knowledge in any department of science has almost passed away, for, except in isolated cases, in any process where the demand for the result is pressing, it is more than difficult for the manufacturer to prevent some clue falling into the hands of others. Moreover, our patent regulations are at least sufficiently stringent to remove serious objection from this side of the question. Of course, no manufacturer would give countenance to the exposure of the results of experiment while these results were still experimental and unpatented, whether the account were from his own laboratory or illicitly from that of others. Another point is that manufacturers would for their surplus stock of information on points useful to others gain an interchange from the surplus stock of others information useful to themselves.

The Association, it is needless to remark, would in no way trespass upon the ground occupied by the Chemical Society, for it would discuss questions of prime cost and market price that a purely scientific society cannot consider. But we need not argue upon contingent results alone, for, besides the Iron and Steel Institute mentioned by our correspondent, we could indicate several instances of the benefit accruing to manufacturers from their combination; indeed, it may be asked, is not the advanced state of technology an effect of combination, either actually or virtually, by means of quickened channels of communication. Many other inducements to the formation of such an association, some of which have been hinted by our correspondent, we cannot consider here, nor is mention necessary, for they will form individual incentives to the consummation of the proposal.

Finally, we throw open the columns of the CHEMICAL NEWS to the discussion of preliminary arrangements, and earnestly invite the correspondence of Manufacturers and their Managers upon the subject, feeling that in so doing we are co-operating with them in advancing the interests of chemical industry.

CHEMISTRY AND THERAPEUTICS.

In an address on this subject delivered last year by Dr. Hofmann to the Medico-Chirurgical Society of Berlin, the lecturer gave an account, at the outset, of the progress of chemistry in study of the hydrocarbons, and showed how chemical analysis had led to a knowledge of the active principles of medicines that had long been in use. Referring to the advantages accruing to therapeutical science from a study of chemical transformations, he spoke to the following effect:—

"There are a number of substances which can be extracted from organic matter only in very small quantities, and in a somewhat impure state. The study of chemical transformations enables us to obtain large quantities of these perfectly pure, and with little expense. Discoveries of this kind form a very interesting episode in organic chemistry."

During the last thirty or forty years the attention of chemists has been largely directed to alcohol; and the researches of Dumas and Liebig on the subject are well known. Dumas discovered in wood-spirit a new alcohol, having properties analogous to those of spirit of wine or *ethylic alcohol*, and he gave it the name of *methylalcohol*. The chemists then began to see that they had in these two, ethylic and methylalcohol, the prototype of a large class of substances, the most important among organic combinations. Then commenced an eager search after new alcohols, which has hardly abated up to the present. The various parts of organic chemistry have been explored with this object, and the search was not long without result. In an oily liquid obtained in the manufacture of alcohol, as an accessory of the fermentation of sugar, and which, on account of its bad smell, is carefully separated from the spirit of wine, Cahours found a third alcohol, and the rejected product came to acquire high scientific importance. This was *amylic alcohol*; also found in oil of potatoes. It has all the properties of other alcohols,—and when subjected to oxidating agents, produces an acid, in the same way as methylalcohol is changed into formic acid, and ethylic alcohol into acetic acid. What was the surprise of chemists, on finding that this acid was the same as that obtained in very small quantities from the root of valerian! And as soon as science showed that this expensive substance could be prepared from oil of potatoes, it became the object of an important industry. Its salts, especially the valerates of zinc and bismuth, are now largely used for medicinal purposes.

Among the organic acids earliest known to chemists was *lactic acid*. Scheele first observed it in acid milk; it was afterwards found in gastric juice, sourkrout, and the juice of cucumbers. But it was not till the relation between sugar and lactic acid became known, and the acid was proved to form only at the expense of saccharine matter; it was not, in short, till the conditions of its manufacture were known, that it was introduced into therapeutics, and now, in the form of lactate of iron, plays such an important part.

A similar case is that of *succinic acid*, though it is not so much used in medicine as lactic acid. It was formerly obtained by dry distillation of yellow amber, but in very small quantities, and with many impurities. No such costly method is now followed. Analysis proved that the molecule of succinic acid differed from that of malic acid only by the atom of oxygen. Now it was shown by Desaigne, that there is in the berries of the *Sorbus aucuparia* (or quickbeam), an abundant store of malic acid, which can be transformed into succinic acid by a simple process of fermentation. All the succinic acid of commerce is produced thus.

The manufacture of *benzoic acid* has undergone a transformation not less remarkable. The nature of this acid only began to be known in the end of last century. It was formerly extracted almost exclusively from

benzoin; but very little of it is now obtained in this way. In 1829, Liebig discovered in the urine of herbivorous animals the acid called *hippuric acid*, and which is transformed by fermentation into benzoic acid. Later, Desaigne proved that the same transformation was obtained by boiling with concentrated hydrochloric acid, in which process a very interesting secondary product is obtained, viz., *glycocol*.

Another acid deserves notice, though less important in therapeutical science, viz., *formic acid*. Chemists have found in distillation of oxalic acid, a source which furnishes this acid much more readily and in a purer state than the bodies of the insects from which it takes its name.

The remarkable properties of *glycerine* are ever finding new applications in pharmacy. It was discovered by Scheele in 1783, but it is only since the classical labours of Chevreul on fatty substances have enabled us to understand, in all its simplicity, the process of saponification, that the industrial preparation of fatty acids and of glycerine has been undertaken with success. Since the adoption of aqueous saponification, the employment of glycerine has been largely extended.

And it is not only from the direct employment of glycerine that therapeutical science has reaped advantage; it has also been benefitted through the study of its transformations, which chemists have recently investigated with great success.

It has been long known that the irritating properties of the flour of mustard are due to an æthereous oil, which may be obtained by distilling mustard with water. M. Will determined the nature of this oil. He found it to contain, in combination with sulphur and cyanogen, an organic radical called *allyl*, and which had already been met with in other substances,—in oil of garlic *&c.*, where it combined with sulphur to form sulphide of allyl. In studying the action of iodide of phosphorus on glycerine, Berthelot observed the formation of a substance in which this radical unites with the iodine to form iodide of allyl; and thereupon occurred the idea of accomplishing the synthesis of oil of mustard or allylic sulphocyanate, by causing a metallic sulphocyanate to react on iodide of allyl; and, in fact, by distilling this iodide of allyl with sulphocyanate of potassium, oil of mustard is obtained with all the characteristic properties of that which is furnished by the plant. Oil of mustard is now mostly prepared in this manner.

Another synthesis may here be briefly alluded to. The *Cochlearia officinalis* furnishes an oil known to pharmacists as spirit of cochlearia. This oil has recently been shown to have a constitution analogous to that of oil of mustard. It is *sulphocyanate of butyl*; a combination which is easily produced artificially.

The instances that have been cited may suffice to show that the study of transformations in organic substances has been the origin of more simple and less costly methods for the preparation of substances the curative effects of which experience has demonstrated.

A. B. M.

WHAT IS THE ATOMIC WEIGHT OF INDIUM?

By S. E. PHILLIPS.

THE popularisation of science is one of the cheering aspects of the present age, and the Royal Institution is at once one of the highest and most efficient of guides in the new department. The science of chemistry has two parts, which often wisely involve distinct professorships: one of laboratory manipulation,—the technical art; the other of chemical philosophy, whose aim is the collocation and orderly arrangement of the accumulating infinitude of facts. With an ardent and loving aptitude for manipulation and details, the amateur is not absolutely excluded from the former; but his more legitimate

position is undoubtedly with the latter. The rôle thus assigned is, however, one of extreme difficulty, apart from the conflicting necessities of daily life and business; and he is often compelled to proceed with a trembling uncertainty from the paucity of means of research.

It was under this impression that I offered some brief remarks on the character and limitations of the factors which conjointly determine the atomic weights of chemical science (CHEMICAL NEWS, vol. xxv., p. 63), and the same feeling now prompts the present inquiry.

All Professor Odling's efforts have a characteristic neatness, elegance, and force, commensurate with his high position and attainments; it is therefore the more un- welcome when an outside amateur cannot indulge in unmixed admiration. Although "the quantity of indium which unites with 8 parts by weight of O and with 35.5 of Cl, was found by Winkler to be 37.9 and by Bunsen 37.8," yet up to very recently the atomic weight has been regarded from the diatomic point of view, and recorded as 75.6. Of the reasons for this I am wholly ignorant, and it now appears that the vapour density has not yet been determined!

The notations given were thus—

In 76.53		2KCl+InCl ₂
Nitrate		In+2NO ₃
Sulphate		In+SO ₄

A cursory glance of these types naturally suggests the following, in old notation:—

		KCl+InCl
Nitrate		InO+NO ₃
Sulphate		InO+SO ₃

Meanwhile M. Bunsen has determined the specific heat constant to be 4.3 instead of the hypothetic normal of 6.5, and, multiplying the atomic weight by 1½, he gives the following:—

In 113.4—		In 37.8.
The chloride.. ..	InCl ₃	InCl
The yellow oxide..	In ₂ O ₃	InO
The normal hydrate	InH ₂ O ₃	InO+HO
The nitrate	In(NO ₃) ₃	InO+NO ₅
The sulphate	In ₂ (SO ₄) ₃	InO+SO ₃
The black oxide ..	InO ₂	{ InO+In ₂ O ₃ or In ₃ O ₄

which I have compared with my *a priori* projection. The manuals published in 1869-70 state that indium is 75.6, and combines with 2Cl, &c. Those in 1870-71 affirm its atomic weight to be 113.4, and that it is tri-atomic, &c. And the burden of my inquiry is, whether this easy method of altering the alphabet of the science, without a careful regard to all the factors which affect the result, is wise.

Among these factors, and in addition to the non-volumetric determination, I complain not that the Professor has omitted all reference to the specific refractive index, but I do take exception to the invalid apology for excluding the all-important reference to the chemism of the subject, as also a total disregard to the simple and crucial electro-lytic determination.

On the contrary, I maintain that the general types of combination are determined by the position in the electro-series, and that a glance at the above notations naturally suggests the hypothesis of a mono-chloride rather than a bi- or tri-combination. While thus apparently ranking with the lowest and simplest type of salts, yet the black oxide would indicate a high position in those relations, perhaps considerably above either hydrogen or copper. At the same time it must be confessed that from such a slender series only very provisional indications can be fairly deduced, and the danger of reasoning in a vicious circle herein should be sedulously suspected.

It may be well, before attaching value to such indications, to compare the stranger with some well-recognised

bi- and tri-atomics. Gold, in relation to O or Cl, is most definitely tri-; but that it is so *per se*, or that it therefore is equivalent to or replaces 3H, is a matter of which I find no evidence whatever. Any present list of gold combinations, or any imaginary slender list, before its relations were so well understood, would exhibit auric acid AuO₃ or AuCl₃, as more like sulphuric acid than any imaginary oxide or chloride of indium. Or, if we similarly compare the well-known binoxides or bichlorides of mercury or platinum, and try to divest ourselves of the accumulated facts in illustration of their electro-positive or combining functions; how very early it was seen that these chlorides tended to the formation of negative or acidulous characters in the chloro-platinates, &c.

If indium becomes a normal tri-oxide or tri-chloride, then its electro-position must be higher than mercury or platinum, or even carbon; and where are the facts leading at all in this direction? Its slender provisional portrait gives no such indications, and its weakly basic character is proclaimed in every feature. But then M. Bunsen says its specific heat constant is 4.3 instead of 6.5, and that its atomic weight must be multiplied by 1½. Be it so, if other factors point in the same direction, but the corresponding constant of chlorine is exactly 4.3, and that of nitrogen and hydrogen rather less, and there is no attempt to make these conform!

Referring to the volumetric factor, N is one vol., and its close chemical analogue P=½ vol. Now this anomaly vanishes in their compounds, and ammonia or phosphonia both equally evince the normal 2 vols. Had this mysterious multiple discrepancy, of which we have many other instances, been ruthlessly rectified, as some have wished, by a doubled atom, then, besides disturbing the whole range of chemical congruities, all subsequent combination volumes would have been similarly deranged.

I anticipate that a similar state of things will be found to subsist with the similar multiple variations of the specific heat factor; and that the mysterious initial discrepancy will often vanish in the compounds, or conversely be disturbed in cases where inconsiderate changes have been made in violation of other and higher elements in the equation.

I am very sorry to be tempted to speak in advance, and to reason so much on such a restricted basis of fact, because a fuller knowledge may show that the normal chloride of indium is either a bi- or a tri-combination; but my inferences from the present limited facts are—

1. That the weight of indium exchanged in the voltaic circuit will be 37.8.
2. That the weight which corresponds to or replaces one H or other analogous element, in substitutional types, will be 37.8.
3. That the volumetric determination may be in agreement with that of H, either initially or in some of its compounds, and represented by 37.8.
4. That the electro-position and consequent reactions will bespeak a status adjacent to, but lower than, aluminium.

One word, in conclusion, on the studied suppression of the chemism of the subject, a factor of by far the greatest value in the whole series. How characteristic this is of modern methods we have pointed out in respect of the Hofmann treatise.

"He uses the word Chemism to express the dynamical or atomic forces involved—as we think—in all chemical phenomena; but the reference is only made once, near the end of the book, and then only in a parenthetical way, as if to show its irrelevance, while portraying the atomic or diatomic mechanism of varied atomicities, varied quantivalences, of atom-fixing powers or points, &c."

In regard to the higher value of the volumetric consideration, it should be observed that the protochloride of mercury is 2 vols., as well as the bichloride; and, still further, that the really corresponding chlorides of platinum are both 1 vol.!

* Professor Odling's Lecture at the Royal Institution, "On Indium," (CHEMICAL NEWS, vol. xxv., p. 266.)

It may suit a numerical progression to treat it otherwise, and double the atoms to get the required volume, but what are the chemical facts? The chlorhydrargates and chloroplatinates, with the corresponding oxy-salts, are all strictly analogous both in type and function, although constituted of such diverse volumetric metals; and, what is far more to the point, these atoms or equivalents similarly exchange in the voltaic circuit, and their chemical substitutions in varied ammonias or other hydrocarbon radicals similarly correspond; and the implied $\frac{1}{2}$ vol. Pt quite agrees, both chemically and volumetrically, with the 2 vol. mercury.

Chloride of
Ammonium.
 $H_3H\ NCl.$
 $H_3Pt\ NCl.$
 $H_3Hg\ NCl.$

Chloride of
Atomium (type).
 $H_6H\ N_2Cl.$
 $H_6Pt\ N_2Cl.$
 $H_6Hg\ N_2Cl.$

Similar considerations apply to the aluminium chloride, which Dr. Odling gives as a trichloride, but which modern entanglements mostly regard as a hexachloride.

The Mendelejeff-Odling tabular series, however, bristle with such incongruities, and demand a separate notice.

ON ÆSCULIN.

By ROBERT F. FAIRTHORNE.

THIS principle is easily separated by the following process:—A quarter of a pound of horse-chestnut bark in moderately fine powder is moistened with half a pint of a mixture composed of three ounces of solution of ammonia (U. S. P.), and five ounces of water. This is packed in a glass percolator, in the neck of which a plug of cotton has been placed. A pint and a half of a weak solution of ammonia is poured on the bark, and allowed to pass slowly through.

The first half-pint of the liquid that displaces is set aside in a capsule and evaporated spontaneously until reduced to a syrupy consistence. The remaining pint is brought to the same condition as the first portion, by means of a sand-bath and gentle heat. These products are then mixed with one and a quarter ounces of pure alumina by rubbing together in a mortar. Allow the mixture to dry, which requires a few hours. Powder the dried mass, and boil it for five minutes in a flask with six ounces of alcohol (95 per cent). Filter this whilst hot, and pour six ounces more of boiling alcohol on the residue in the filter. Place the filtered liquid in an evaporating dish, and allow it to evaporate spontaneously until reduced to a semi-solid state, when impure æsculin will be found in a crystalline condition contaminated with some dark-coloured extractive matter.

In order to separate the æsculin from the colouring matter without loss, mix two ounces of cold water with it in the capsule, and having scraped it thoroughly from the bottom of the vessel, pour it into a vial. Add one fluid ounce of ether to this, and agitate for a few minutes. Allow it to remain undisturbed for twenty-four hours. Afterwards pour the mixture on a filter, and when the dark-coloured fluid and the ether have passed through, wash with about two drams more of cold water.

The æsculin is now nearly pure. In order to make it perfectly so, all that is necessary is to allow it to dry in a warm place, powder it, pass half an ounce of pure benzole through it after having been placed on a filter; then treat it in the same manner with an ounce of ether so as to remove any pavin that may be present, that substance being readily dissolved by ether.

Sixteen grains appears to be the average weight of the purified active principle obtained from 4 avoirdupois ounces of the horse-chestnut bark by this process. After trying various methods for extracting æsculin, I found none so satisfactory as this one, either in regard to simplicity, the quantity yielded, or the quality of the production.

Æsculin, as thus prepared, appears to the unaided sight, as an amorphous powder, almost white, being of a slightly pale buff shade. Under the microscope (magnified 220 diameters) it is proved to consist of minute needle-shaped crystals.

From its alcoholic solution its crystals arrange themselves in stellular tufts, the aciculæ, pointed at the ends, radiating from a common centre in every direction, forming a very beautiful object, the transparent prisms glistening with more than ordinary lustre.

I find that it is soluble in the following liquids:—Alcohol, acetic ether, strong acetic acid, solution of carbolic acid, solution of the hydrate of chloral, and in the alkaline solutions.

When æsculin is added to nitric acid it becomes yellow, and if ammonia in excess is added to this mixture a bright cherry-coloured liquid is produced. When sulphuric acid is substituted for the nitric acid, and ammonia added, the same colour appears.

NEW MEANS OF SEPARATING AND UTILISING THE PHOSPHORIC ACID FROM IRON ORES.

By JULIUS JACOBI.

Director of the Smelting Works at Kladno, Bohemia.

THE method of working proposed by the inventor, consists in changing the insoluble basic phosphates contained in the ores into soluble acid phosphates, and the separation of the soluble phosphates, by a simple process of leaching.

In order to attain this result, the ore is treated with a compound of sulphur and oxygen usually most advantageously and cheaply with sulphurous acid in the gaseous state or in solution, for which purpose a very dense ore must naturally be pulverised, a pyritous ore or one containing carbonic acid must be well roasted by well-known methods, while a porous ore which allows the penetration of the liquid into the pores, can be used in pieces of moderate size. The ore thus prepared is placed in receivers the size and shape of which must be dependent on various conditions, and water impregnated with sulphurous acid is turned upon it, or the sulphurous acid gas is conducted at once to the ore, while a stream of cold water is turned upon it at the same time, so that the absorption of the sulphurous acid into the ore takes place through the medium of the water.

The latter would be especially good with porous ores, since the gas readily enters the pores, and its operation would therefore be more rapid.

Moreover, as a simpler and more rational mode of working, the sulphurous acid might be forced under pressure into the solution.

The solution after this operation should stand over the ore until no further reaction takes place, and until the greater part of the phosphoric compounds has passed into solution. It is very important to observe this carefully, and not to allow the reaction to continue too long, since otherwise phosphates may be again precipitated. The solution is then drawn off, and replaced by water, which will remove the salts rendered soluble but not previously removed. This washing is continued as long as phosphoric acid may be detected in the wash water. If phosphoric acid still remains in the ores, the same process may be gone through with once or several times more, according to the degree of purity required for the ore. It is evident that the duration of the operation must be regulated by the amount of phosphate in the ore, and its porosity. After the last treatment with acid, the ore must be well washed with water, to remove all traces of the acid.

The water remaining, after each treatment, which contains the phosphorus compounds, is collected and heated

directly by a naked fire, or by passing steam pipes through it, in order to drive off the sulphurous acid, by which means a portion of the phosphates will be precipitated. The sulphurous acid thus driven off may be allowed to escape into the air, or if one is economically inclined it may be again united with water and used over again. The liquid, in which by heating a portion of the phosphorus compounds have already been precipitated, is then treated with burnt lime, and allowed to stand until the whole precipitate, which contains all the precipitable substances, has settled to the bottom of the tank. The addition of lime is of course only necessary when, by heating the liquid to drive off the sulphurous acid, all the phosphorus compounds are not precipitated, which is the case with many ores. Thereupon the clear liquid is to be drawn off, and the deposit, when it has attained the right consistency, removed. This is now, on account its containing phosphoric acid, a very valuable product for agriculture and the arts, and may be sold for direct application in agriculture, or for further working up. In many cases the proceeds from this sale will cover a large part of the expense of treatment. The preparation of the sulphurous acid is effected by some known method from sulphur, pyrites (where these are to be obtained cheaply) or from other similar substances.

The purified ore should be taken from the receivers and treated in shaft furnaces, when a good pig-iron will be obtained. If the ore has been previously pulverised it is well, before charging it into the furnace, to make it into bricks by the use of lime or some other cementing material.

By the removal of the phosphorus compounds the iron ore becomes somewhat richer in iron, as well as purer.—*Bayerisches Industrie und Gewerbeblatt.*

ON THE RESULTS OF DISINFECTION ON THE BATTLE-FIELDS IN FRANCE.

Report of C. JUNGHAUS.

IN the month of October, commissioned by the Directory of the German Chemical Society at Berlin, I visited the environs of Metz, and was during most of the time actively engaged in the work of disinfection upon the battle-fields of Saint Privat, Amanvilles, and Bernéville. The means at command for the accomplishment of this work were chloride of lime, manganese lye (the acid residuum from the manufacture of chlorine gas), and carbolic acid in large quantities. Besides these, green vitriol and a disinfecting powder, which contained carbolic and green vitriol, were also on hand in smaller quantity.

The trench graves (*massengraben*) on these fields were very numerous and near together, often concealing from one to two hundred bodies apiece. For these, and for the great number of horse carcasses lying buried almost everywhere, it was necessary to obtain, with the means at our disposal, a disinfection which should be not only immediate, but effectual for a long time. For this purpose, a prompt and copious flow of chlorine gas was procured from chloride of lime and manganese lye, and applied in the following manner to the large burial mounds. Upon each of these mounds, on which the earth lay to a depth of from 1 to 3 feet, a long trough was dug with a spade; into this the rich manganese lye was allowed to run. Chloride of lime in large quantities, sometimes reaching 500 lbs., was then thrown in, the channel covered with earth, and the mound strewn widely with chloride of lime. Earth was then thrown over all, and the hill heightened where necessary. After ten or twelve days, as long a time as it was possible to extend the observations, a distinct chlorine smell was perceptible at a distance of about one hundred paces from the place where several of the burial

mounds so treated lay close together. This smell was more particularly noticeable after a hard rain, which brought the chemicals together in solution.

It was fully proven that manganese lye by itself is a powerful disinfectant. Several horse carcasses which, like all the rest, were much further gone in decomposition than the human bodies that we encountered, and which emitted a very great stench, were abundantly sprinkled with manganese lye alone, for on that day we were not able to add any chloride of lime. After several days, when we returned to work again upon this place, all stench had disappeared. It should be mentioned that the lye was used undiluted, just as obtained from the Union Chemical Works, at Mannheim.

The carbolic acid, which was a better quality of the crude acid of commerce, said to contain 60 per cent of pure acid, was also applied to the horse carcasses. This application was continued as long as the supply would permit, in connection with green vitriol and the disinfecting powder. Those carcasses which lay mostly uncovered, or on which earth had been thrown as they lay, were, as far as possible, sprinkled directly with carbolic acid. Either green vitriol or the disinfecting powder was then put on, and the earth thrown up over the whole. Certainly no immediate disinfection could be obtained with the carbolic acid, highly prized though it be for retarding putrefaction. This was all the more true when the green vitriol and disinfecting powder were applied along with it. The stench in these cases was finally dispelled by a single application of chloride of lime, so that no renewal could be perceived. These points were especially observed in the case of a large number of carcasses lying in a stable belonging to the farm-house of Champénois, at Bernéville, which had been destroyed by fire. It was not possible to cover them with earth. It was in its application as an antiseptic to these great masses of flesh, which in all probability even now are no better interred, that carbolic acid was most constantly useful.

From these observations and experiences obtained on the spot, I think I may draw the conclusion that it is advantageous, in cases of this kind, to saturate thoroughly, as early as possible, the earth overlying the graves with salt solutions that have the power of absorbing or destroying gases. Green vitriol and manganese lye possess, in addition to their well-known efficacy, the advantage of cheap production. If foul gases have already escaped, the immediate application of chloride of lime is the most convenient means for their destruction.

Bromine, just as energetically efficacious as chlorine, has already been advantageously applied to the disinfection of foul-smelling waters. It is too volatile to use on the graves of battle-fields, besides being difficult of application.

Horse carcasses, which unfortunately are always badly interred, should be at once impregnated with carbolic acid. For this purpose it is sufficient to sprinkle the acid upon the ears and abdominal cavity, and upon the immediate surroundings of these parts.

A careful burial, however, without too much crowding, is undoubtedly the most certain way of preventing subsequent evil consequences, even if it require the expenditure of a great amount of time and labour. A very great deal has been done in time of war by the authorities and by private individuals from motives both humane and selfish. A proper burial of the victims of the war is, however, yet to be secured.—*Dingler's Polytechnisches Journal.*

Oldham School of Science.—A laboratory for the use of students in practical inorganic chemistry having been opened at the Oldham School of Science and Art, twenty-one artisan students presented themselves for examination by the Department on the 3rd of May, and nineteen of them have passed.

NOTES FROM THE INTERNATIONAL
EXHIBITION OF 1872.

In the absence of an Official Report upon the Recent Scientific Inventions and New Discoveries exhibited at South Kensington this year, we present to our readers a short account of the principal features of this department of the Exhibition. Entering from Exhibition Road, we are at once within the precincts of that curious collection, the Indian Court. This court has a relative interest for the scientific visitor, because as here represented the majority are the results of hand-labour, while the remainder of the building is devoted to the products chiefly of machinery, or to the machinery itself and its construction. The Indian contributor presents to us those elaborately carved caskets, the delicate filagree work in gold and silver, for which he has been justly celebrated through so many ages. There is, too, a case of native musical instruments, and these, though perfectly beyond our comprehension in other respects, show that there has been much careful thought expended upon the construction of their gourd-shaped resonant chambers. At the end of the Indian Court is the entrance to the Stationery Department, and here are exhibited the process of Heliotype Printing by the Heliotype Company and the Woodbury Process by the Permanent Printing Company. Mr. S. H. Cowell has here a process, termed Anastatic Printing, which appears suited to many useful applications. The design drawn upon ordinary paper with the prepared ink is transferred from the paper to a metal plate, from which an indefinite number of copies can be produced, the invention being intended to supersede lithography. Appropriately Messrs. Parkins and Götto exhibit on the opposite side of the room a Lithographic Printing Machine by Mr. S. Barrett, as well as machines for cutting and stamping paper. In the next room are exhibits illustrative of the process of paper-making, but to the chemist there is nothing of interest, excepting the Pulse Pump for laboratory use of M. Mendelejeff, to which is, however, appended very little information, a remark equally applicable to an interesting Thermo-Electric apparatus in this room. Passing a long array of cases containing some elaborate specimens of Valentines, writing-cabinets, stationery with every variety of device, &c., a case containing specimens of half- and whole-stuffs for paper-making, we enter a gallery lined with newspapers and periodicals in all languages, from Greek to Gaelic, from Hungarian to the equally unpronounceable Welsh. This corridor conducts to the room devoted to scientific inventions, and we are immediately before the table at which the attendant explains the uses of the Fire-proof Starch, and shows how readily unprepared muslin may be ignited, while muslin starched with the Fire-proof Starch only smoulders. The starch can be supplied at 8d. per lb., certainly cheap enough for use where there is more than ordinary risk, as in ball-dresses or bed-room hangings. The colour, Messrs. D. Nicoll and Co. state, is the same as with other good kinds of starch, and the fire-proof starch contains no ingredient of any kind unpleasant or prejudicial to health and comfort. Farther in the room we have Colonel H. Stuart Wortley's Results of New Dry Photographic Process for working by the use of collodio-bromide of silver without a silver-bath. The plates are very clearly defined, and we wish they were more numerous. Near at hand is a Foul Air Purifier for sewers, exhibited by Mr. Ludstone, and consisting of a ventilating lantern containing charcoal or the disinfectant. With M. Leon Delperdange's Cylinder for conducting Telegraph Wires Underground there is exhibited a Telegraphic Apparatus, founded upon Morse's system, the invention of M. De Torville. This instrument is in use upon some Russian lines, and is very simple in construction, the whole of the apparatus being arranged upon a small table, in the interior of which is some mechanism for winding up and drawing forward the

paper slip as it is printed. On the wall are diagrams in which Dr. Karl Ticsinsky propounds the Quadrature of the Circle, a matter not very interesting to the visitor. Sir Joseph Whitworth and Co. exhibit models of a Breech-loading Naval Gun and a Breech-loading Field Gun and Carriage, as well as a Six-pounder Breech-loading Rifled Gun and Carriage made of Sir Joseph Whitworth's Patent Compressed Metal. Messrs. Siemens Brothers and Loeffler exhibit Dr. Siemens's Apparatus for Working Pneumatic Despatch Tubes, on the continuous current system, as established for the transmission of postal telegrams between the West Strand and Central Telegraph Stations, together with an Exhauster or steam-jet arrangement for drawing the air through the tubes. Dr. Siemens also exhibits his Deep Sea Photometer, for comparing the intensities of light at different depths of water. The apparatus was very successfully used on board H.M.S. "Shearwater," in August, 1871, for comparing the intensities of light at different depths of the Straits of Gibraltar. Further in the centre of the room is a valuable collection of acoustic apparatus by Messrs. Lefèvre, of the Hague, but the utility of the invention cannot be made apparent without diagrams. Lieutenant-Colonel Clarke, C.B., R.E., has a model of Three-legged Shears admirably adapted for a wharf too narrow to admit of the back leg traversing horizontally in the usual manner. Mr. Bessemer exhibits a very complete series of sectional models illustrating the Bessemer principle of constructing Continuous Low-Pressure Ordnance; while Major Palliser's contribution of a Service Muzzle-loading Sixty-four-pounder Rifled Gun, converted on the Palliser principle from a smooth bore thirty-two-pounder gun, and having fired 2300 rounds, may be considered to complete the artillery exhibits, together with the specimens of Gunpowder, recently tried by the Committee on Explosives, and a Crusher Gauge for directly determining the pressure of fired gunpowder, both by Captain W. H. Noble, R.A. Distributed through the room are models of the Newport Patent Puddling Furnace, exhibited by Mr. Jeremiah Head; a Patent Hot-Blast Fire-Brick Stove, exhibited by Mr. T. Whitwell; a Kiln for burning bricks, lime, cement, &c., by Mr. A. Batchelar; and Mr. Danks's Patent Puddling Furnace. Messrs. Lynch and Co. exhibit a knobbed Poison Bottle to prevent use of poison by mistake in a dark or dimly-lighted room.

The actual results of chemical processes are very scantily represented, being confined chiefly to the preparation of the pulp for paper making. Mr. F. B. Houghton exhibits a series of four bottles illustrative of the manufacture of pulp from wood, in reference to recovering the alkali without evaporation or calcination. The liquor in which the wood has been boiled to disintegrate the fibre is treated for the coagulation of the resin, the remanent liquor being treated as if it were new soda-ash, and the resin as a valuable by-product. Permanganate of soda is preferred as a bleaching agent by the inventor. There are also drawings of Apparatus for Recovering Soda used in Preparing Fibre for Paper making, which obviously we cannot copy here; they are exhibited by Messrs. W. W. Ladelle and A. G. Southby. Messrs. B. Donkin and Co. exhibit an enormous Spherical Boiler for boiling and washing rags, hemp, straw, &c., for paper manufacture. There are two Non-conducting Cements for covering boilers and steam-pipes, exhibited by Messrs. Leroy and Co., and by Messrs. Fox, Head, and Co. Almost at the end of the room is the model of a house or shed constructed of waterproof paper, and exhibited by The Universal Paint and Waterproof Fibre Company, the paper being rendered waterproof by the Patent Cupro-Ammonium Process, of which the company are the licencees. Cupro-ammonium is, we believe, an arbitrary term, the material being prepared by the immersion of copper turnings in concentrated liquid ammonia, with access of air. After some time the ammonia is stated to acquire a deep blue colour, and peculiar agglutinating or solvent properties. Paper or almost any

fibrous substance dipped into this liquid becomes so far reduced, that by being pressed upon itself, or upon another sheet similarly prepared, a solid mass of any required thickness can be obtained. Copper-oxide dissolved in ammonia is said not to have the same solvent action. Paper may thus be rendered waterproof, being afterwards corrugated for roofing purposes, &c., at an increase of 40 per cent upon the original cost. Mr. H. Deacon contributes drawings of his Method of Obtaining Chlorine. The process consists in passing a heated mixture of air and hydrochloric acid over sulphate of copper, or over pieces of pumice or brick saturated with a solution of this salt. The velocity with which the mixed gases pass over the surface of the active material causes considerable variation in the comparative amount of chlorine produced.

The electrical exhibits of this year are by no means numerous. Leaving the room devoted particularly to scientific inventions, and which we have almost exhausted, we meet with the Electric Motor Clock of Messrs. Cooke and Son, of York. This clock has now been driving the clocks in the several rooms of the Exhibition for two years; to those who know the difficulties of electric horology a sufficient recommendation. In the French Court is exhibited by Messrs. Moseley and Son a novel form of Electric Clock, in which the electric current is called into action only when the oscillations of the pendulum are decreasing; by this means the consumption of materials in the electro-motive element is reduced to a minimum, and the regularity in keeping time ensured for a longer period.

The first actual application of electricity to the uses of organ construction was made by Mr. Barker, of Paris; and Messrs. Bryceson Brothers and Co., seeing the great advantages which the system offered, introduced it into England in the organ built by them for Her Majesty's Opera in 1868. In churches, halls, &c., many positions can be utilised by this system that were formerly utterly impracticable. The organ exhibited in Room 13 is played by electricity, the organist literally telegraphing his manipulations through a cable. An electric current is completed round its corresponding magnet by pressing a key, and the armature being attracted causes the pallet to open and admit wind to the pipes. By an automatic arrangement the electrodes of the four cells of the single fluid battery employed are withdrawn from the exciting fluid when the wind is out of the organ, so that all waste of chemicals is suspended. We must, to be fair, acknowledge the superior workmanship of the ordinary manual organ of Messrs. Jones, whose instrument has met with unanimous commendation from the musical critics; and we cannot leave this portion of the exhibits without noticing the elaborately inlaid pianofortes of Messrs. Hopkinson and of Messrs. Erard. Messrs. Erard's instrument is exhibited in the French Court, and its interest is due to beauty alone; but the pianofortes of Messrs. Hopkinson embody an application of iron in the construction of what is termed "the back" of the instrument, decreasing the liability to get out of tune, especially in hot climates. This firm also exhibits some smaller instruments of extreme brilliancy and fullness of tone, to which the musical critics have accorded high commendation.

The exhibits offering the greatest attraction to visitors are undoubtedly the various newspaper presses. The "arte and mystérie" of printing has had its special interest for all ages of its use; and there are two machines in the present Exhibition, types of the wonderfully rapid progress that has been made since 1474. We allude to the Marinoni printing press, turning off its 12,000 copies of the *Echo* hourly; and to the "Walter Press," which derives its name from the enterprise and perseverance of its inventor, Mr. Walter, M.P. By this machine, the *Times*, the *Mail*—a tri-weekly reprint of the *Times*, and the *Scotsman* are now supplied to the public, with very little manual labour. The Walter Press is

what is termed a "perfecting" machine, printing both sides of the sheet at one operation. The details of the machine are very simple. At one end of the framework of the press is a roll of paper several miles in length. This paper is led from the roll into a series of small cylinders, where it is damped. It is then brought between the first and second of four cylinders, supported above each other perpendicularly in a powerful framework. The highest of these cylinders is encircled by the stereotype casts from four pages of type, and the lowest cylinder is similarly surrounded by the casts of the type of the remaining four pages of the newspaper. Between the highest pair of rollers one side of the paper is printed; then passing backwards between the second and third cylinders, it is again drawn forward between the third and fourth cylinders, receiving an impression on the opposite side from the latter cylinder. The printed paper passes to the cutting cylinders, where it is cut into sheets. The manual labour required is therefore limited to the attendance upon the apparatus distributing the printed sheets, since the machine is self-feeding from the continuous roll of paper. The paper passes through the machine at the rate of nearly 1000 feet per minute, so that a roll of paper four miles long (as supplied by the paper mill), is printed and taken off in less than twenty-five minutes. The matrix of the type is taken from the whole page at one operation in *papier maché*, being rapidly dried upon heated surfaces. Into this mould stereotype metal is poured, the entire operation being completed in thirteen minutes. This marvellous celerity has been attained by careful investigation as to the best alloy for the stereotype metal, which, at the same time, must be readily fusible and sufficiently durable to stand the wear of many thousand impressions.

We should much like to notice the stoneware and other exhibits, but from a scientific point of view there is nothing further that calls for the extension of our description last year.

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.*

By Dr. F. CRACE CALVERT, F.R.S.

Red Colouring Substances.—Madder.

THIS well-known tinctorial substance may still be considered as the most important of all the dye-stuffs employed by calico-printers, owing to the brilliancy of the colours, and their permanence under the action of light and soap, and the wear and tear which fabrics so dyed can sustain, as well as on account of the variety of shade and colour that can be obtained; one dyeing operation being sufficient to produce pinks, reds, purples, violets, puce, and black; and, notwithstanding the competition that madder colours have met with of late years from aniline dyes, I believe the quantity of madder consumed in England is quite as great at the present day as ever it was.

The employment of madder-root as a dye dates from the most ancient times, as is proved by the Egyptians using madder-dyed fabrics to wrap round their mummies. The Greeks and Romans were acquainted with it under the names of *Erythrodanon* and *Rubia*, and their modes of fixing it on cotton fabrics were the same as those now employed, namely, aluminous salts for producing reds, and salts of iron for purples and blacks.

The plant which produces madder is an herbaceous one, and is called *Rubia tinctorium*. It bears a yellow flower, and a dark red berry fruit. The red colouring matter exists almost entirely in the cortical part of the root, little or no colour being found either in the epidermis or in the ligneous or centre part of the root. M. Decaisne

* The Cantor Lectures, delivered before the Society of Arts. Revised and communicated by the Author.

and M. Edouard Kœchlin have shown that the colouring matter in the fresh root is yellow, and becomes red under the oxidising influence of the atmosphere. The same process goes on, to a certain extent, in the roots of the plant when they are allowed to remain several years in the ground, especially in chalk formations. In France, the roots are allowed to remain in the ground two or three years; in Turkey and the East, from five to seven. In the latter countries and in Naples they are dried in the open air, but in Holland and France stoves are employed for this purpose. Naples and Turkey madders are imported in the root, and are known in commerce as Naples and Turkey roots, while those from France and Holland are ground, and sold under the name of French and Dutch madder.

One hundred parts of fresh root yield, on perfect desiccation, twenty parts of dried substance. The roots as imported always contain 16 or 18 per cent of water; the fresh roots, therefore, give 24 or 25 per cent of commercial madder. Dutch and Alsatian madder, after being ground, is stored in large casks, and kept for two or three years, when the colouring matter is developed, and its tinctorial power is much increased: if, however, it is kept five or six years, further changes ensue, and its value seriously decreases. French Avignon madder can be employed at once, although the quality is much improved by keeping it one or two years. The best Avignon madders are grown on lime formations. The roots that have a red colour are called *palus*, and those that are pink *rosés*, the former being considered the finest. The value of these madders is in ratio to the fineness of their powder, the finer powder containing the most colouring matter.

The nature of the chemical changes occurring in madder during the time it is stored, and which so much improves its commercial value, was entirely unknown until the elaborate and interesting researches of Dr. Ed. Schunck, F.R.S., published in the year 1851. He succeeded in isolating a peculiar ferment called *Erythrozym*, which possesses the property of decomposing a substance called by him *Rubian*. *Rubian* may be considered as a glucoside (this name being given by chemists to compounds of sugar with other organic principles), and is decomposed by erythrozym into a peculiar sugar and *alizarine*. Whether there are in the *Rubia*-root several glucosides which unfold themselves respectively into sugar and one of the colour-giving principles, or there is only one glucoside, and its colour-giving principle—as it is liberated—gets successively oxidised into alizarine, purpurine, &c., is not yet satisfactorily determined. Still this valuable discovery of Dr. Schunck has thrown much light on the subject, and has led to several important commercial improvements, to which I shall call your attention as I proceed. One hundred parts of dried madder-root consist of—

Soluble in cold water	55 parts.
Soluble in boiling water, and which contains the greater part of the colour-giving principles	3 "
Soluble in alcohol	1.5 "
Fibrous matter	40.85 "

I shall make no remark on the gum, mucilage, pectine, pectic acid, and pectates, which the *Rubia*-root contains, but state that the water extract contains also the yellow colouring-matter discovered by Kuhlman in 1824, and called by him *Xanthine*; but this colour has never received any commercial application, from its want of brilliancy. Water also dissolves another colouring principle, called *Chlorogenine*, which is decomposed by weak acids into sugar and a brownish-green matter. Both these colouring substances are sources of annoyance to the calico-printer, as they render very difficult the obtaining of pure whites in printed goods, and they dim the brilliancy of the shades produced by the combination of alizarine and purpurine with the mordants. Further, the cold

water dissolves the sugar contained in the root, and on the Continent it is transformed into alcohol. The yield of alcohol varies with the nature of the root, and ranges between 7 and 10 lbs. per cwt. of root. This fact shows that there is from 10 to 15 per cent of sugar in the root.

Messrs. Julian and Roquet have based on the above facts a commercial process for preparing a purified madder, which they call *Fleurs de garance*, of which several million pounds are now manufactured in France per annum. It not only yields brighter colours than the original madder, but, as it does not soil the white parts of prints, its use saves the printer much soap and labour. To prepare the *fleurs de garance* the madder is mixed with 8 or 10 parts of water, and left for three or four days at a temperature of 75° to 80° F., when fermentation ensues, transforming the sugar of the root into alcohol, which is collected. The madder, deprived of all soluble substances, is dried, and ready for use. A hundred parts of madderyield from 55 to 60 per cent of *fleurs de garance*. I may state, *en passant*, that the injury which Dutch and Alsace madders sustain when kept too long in casks is doubtless owing to the fact that, after the erythrozymic fermentation is completed, an alcoholic and lactic one sets in, which acts injuriously on the colour-giving principles.

I now proceed to lay before you the outlines of two interesting processes for extracting commercially the two useful colour-giving principles, *alizarine* and *purpurine*.

The first is due to M. Leitenberger, and is based on the fact that purpurine is soluble in water at 130° F., whilst alizarine only dissolves at 170° F. He mixes madder with water, and heats the whole gradually, by means of a jet of steam, at 130°, at which temperature it is maintained for some time. The liquor is then run off and filtered. To the clear solution, lime—or, still better, baryta—is added, when a lake precipitates. This is washed and mixed with hydrochloric acid. The purpurine thus liberated is thrown on a filter, washed, and is ready for use. The madder remaining from the above operation is dried and heated in close vessels with wood spirit, which dissolves the alizarine. This extract, thus obtained, after being concentrated by distillation, is ready for use. A hundred parts of root yield from 2 to 3 per cent of purpurine, and 4 or 4½ per cent of alizarine.

The second process, that of Professor Emile Kopp, is based on another discovery of Dr. Schunck, namely, that weak acids act upon rubian in the same manner as erythrozym, unfolding it into sugar and alizarine. M. Kopp found, some years since, that sulphurous acid dissolved the glucosides of purpurine and alizarine, and applied this observation as follows:—600 lbs. of Alsace madder are macerated for 12 or 15 hours with 800 gallons of a weak solution of sulphurous acid, to which is added one-thousandth part of hydrochloric acid, to neutralise the earthy carbonates existing in the root. This operation is repeated three times. To the liquors 3 per cent of sulphuric acid are added, and the whole heated to a temperature not exceeding 140° F., when red-coloured flakes separate and gradually deposit, which, when washed and dried, are commercial purpurine. The liquor is then carried to the boil for a couple of hours, and allowed to cool, when a dark green powder is found deposited in the vessels, which, when washed and dried, is commercial alizarine.

This process has been carried out by Messrs. Schaeffer and Lauth for many years, and no doubt yields a larger amount of colour-giving principle than M. Leitenberger's method, the glucosides being doubtless more completely decomposed by the acids than by water alone. It has the further advantage of obtaining the colouring matters free at once, which have only to be washed to be ready for use.

The dyeing power of the alizarine thus obtained is equal to 40 times its weight of madder, or 10 times that of garancine. These colouring substances, except green alizarine, are not substituted for madder in the dyebath,

but are printed on the cloth and steamed, as will be described further on.

M. Kopp found that his green alizarine is a mixture of alizarine with chlorogenine, and that this latter body can be separated by treating the mixture with a light oil of tar, having a boiling-point of 300° , which dissolves the chlorogenine. Alizarine is employed in the production of rich purples, whilst purpurine is used for reds and pinks.

Before describing pure alizarine and purpurine, I may state as a fact very interesting, although of no commercial value, that if superheated steam be passed over a preparation of madder known as garancine, pure alizarine is volatilised, and may be easily collected.

Pure crystallised alizarine was discovered, in 1824, by MM. Robiquet and Colin, by treating madder with strong sulphuric acid, when they produced a black mass, which they called *Charbon de garance*, and which, on being heated at a moderate temperature, yielded crystals of alizarine.

In 1851, Dr. Schunck succeeded in isolating from madder a substance to which he gave the name of *Rubian*. This he effected by filtering a hot decoction of madder on pure animal black, which is washed with cold water to remove chlorogenine. The washed charcoal is boiled repeatedly with alcohol, and the alcohol solution evaporated to dryness. The dry mass is dissolved in water, and acetate of lead added, which gives rise to a precipitate. This precipitate, when acted on by sulphuretted hydrogen, gives pure rubian in solution. When rubian is acted on, either by erythrozym or weak acids, it is decomposed, yielding, according to Dr. Schunck's paper, alizarine and water; according to M. Schützenberger, alizarine and glucose, or grape sugar.

Pure alizarine sublimes, at a temperature of 460° F., into pale orange prismatic crystals. When slowly crystallised from an ethereal solution, it forms a hydrate, containing two equivalents of water, which crystallises in lustrous scales. Cold water dissolves a mere trace of alizarine, but its solvent power increases as the temperature is raised, as may be seen from the following figures:—

At 212°	100 parts of water dissolve..	0.034
At 490°	" " " "	0.820
At 480°	" " " "	3.160

Alizarine is freely soluble in alcohol, ether, wood spirit, benzole, turpentine, sulphuret of carbon, and glycerine. It is soluble without decomposition in sulphuric acid, even at a temperature of 400° F., and is thrown down unchanged when large quantities of water are added. It is soluble in a warm solution of alum, but insoluble in a cold one. It has been assigned different formula by different chemists, the two most generally adopted being that of Dr. Schunck, $C_{14}H_{10}O_4$, and that of Wolf and Strecker, $C_{20}H_{12}O_6$. Alizarine gives a purple colour with a weak solution of caustic alkali, which undergoes no change by the action of air. It yields, with alumina fixed in fabrics, a variety of red and pink shades; with oxide of iron it gives purples and blacks; and, with a mixture of these two oxides, chocolates.

I shall now call your attention to one of the most interesting and important discoveries of chemistry, as applied to manufactures, which have been made of late years, namely, the artificial production of this most important colour-giving principle, alizarine, or of a substance which—if not identical—has great similarity to it. Messrs. Graebe and Liebermann, and Mr. Perkin, believe in the identity of the artificial product with the natural one. But this is denied by M. Alfraise, on the grounds, first, that the formula given by Messrs. Graebe and Liebermann does not agree with that given by Dr. Schunck, as is shown by the following figures:—

Secondly, that the artificial alizarine does not give the

same coloured sublimate as the natural alizarine; and thirdly, that if both these substances are acted on by nitric acid, natural alizarine is converted into phthalic acid, whilst the artificial alizarine, which he calls alizapurine, yields a large quantity of a nitro-compound having an intensely bitter taste, mixed with only a mere trace of phthalic acid. These observations of M. Alfraise have been confirmed by M. Kopp. That the commercial artificial alizarine is not identical with a natural alizarine is rendered still more certain by the researches of Dr. Schunck, who, on examining a sample obtained from Mr. Perkin, found it to contain a large quantity of a compound crystallising in yellow, silky needles, anthraflavic acid, and which he obtained by treating Mr. Perkin's product with alcohol. On treating the acid with fuming nitric acid he obtained a nitro-compound, the potash salt of which he describes as resembling picrate of potash. This is doubtless the bitter principle which Alfraise obtained, but did not study. Dr. Schunck gives the formula of anthraflavic acid as $C_{15}H_{12}O_4$, and considers it homologous to alizarine, one equivalent of its hydrogen being replaced by methyl. Messrs. Graebe and Liebermann, and Mr. Perkin, found their opinion as to the identity of the two alizarines on the fact that they give the same absorption-bands on being submitted to Professor Stokes's spectrum test.

Artificial alizarine was first made in 1869, by Messrs. Graebe and Liebermann. The substance from which they obtain it is *anthracene*, a body discovered by Professor Anderson, of Glasgow. Anthracene is one of the last products passing over in the dry distillation of coal-tar, and is found most abundantly in the 10 or 15 per cent which comes over from the temperature where soft pitch is formed and that where hard pitch is produced. The quantity of anthracene in coal-tar varies greatly; it is most abundant in the tars obtained from those coals which yield most naphtha. The South Staffordshire coals give the largest quantity, whilst the Newcastle coals give very little. Its extraction can only be carried on with advantage in cold weather, as it becomes very soluble on a slight rise of temperature in the oily homologues which accompany it. At a temperature of about 40° the distillate above described is semi-fluid; it is placed in a hydro-extractor, and the oily fluid separates from the solid matter, which is then submitted to cold and hot pressure. The cake thus formed is pulverised and carefully washed with petroleum spirit, having a boiling-point of about 180° , which leaves anthracene moderately pure. This powder, dissolved in alcohol and crystallised, yields anthracene in nearly white scaly crystals, or in a fit state for the manufacture of artificial alizarine.

Messrs. Graebe and Liebermann oxidised the anthracene ($C_{14}H_{10}$) by nitric acid, into anthrachinon ($C_{14}H_8O_2$), this being again converted into bibrom-anthrachinon ($C_{14}H_6Br_2O_2$), which, by fusion with potash, is changed into alizarine ($C_{14}H_8O_4$). There are three patents published, and a process, the details of which are kept secret. It is curious to notice that the patent taken out by the above-named gentlemen and M. Caro is dated June 25th, 1870, while Mr. Perkin entered his on the day following, in which nearly the same processes are described, merely employing different oxidising agents.

The following is an outline of one of the processes detailed in the specification of MM. Caro, Graebe, and Liebermann:—1 part of anthracene is heated with 4 parts of sulphuric acid, of sp. gr. 1.845, for 3 or 4 hours, to a temperature of 212° F., and then for 1 hour at 300° . The mixture is allowed to cool, and to it is added water equal to 3 times the weight of anthracene taken, and manganese equal to 4 times that weight. The whole is boiled for 3 hours, and a milk of lime is then added, which gives rise to a deposit, consisting of the excess of lime and manganese used, and protoxide of manganese, while there remains in solution a double sulphate of anthrachinon and lime. This solution is now acted on by car-

bonate of soda in slight excess, carbonate of lime separates, and the salt of soda thus produced is evaporated to dryness. To this solid mass is then added 2 or 3 parts of caustic potash or soda and a small quantity of water, and the whole heated under pressure, in suitable vessels, at a temperature of 350° to 500° for 1 hour, when the anthracinon is further oxidised, and converted into alizarine. This anthracene, $C_{14}H_{10}$, gives anthracinon, $C_{14}H_8O_2$, and this alizarine, $C_{14}H_8O_4$. The alkaline mass, on cooling, is dissolved in water, and sulphuric or acetic acid added in slight excess, when an orange-yellow flocculent substance precipitates, which, when properly washed and dried, is artificial alizarine.

The second colour-giving principle of madder, to which I have referred several times already, is called purpurine, and was also discovered by MM. Robiquet and Colin, in 1828. Although in commerce it is sold as a red powder, as has been mentioned above, still, by heating at a temperature of 480° F., it can be obtained in the form of feathery crystals, of an orange-red colour. It is more soluble in water than alizarine, especially at a temperature of 140° F., and is also soluble in the menstrua already mentioned under alizarine. Further, it gives a red colour with caustic alkali, instead of purple as alizarine. It is soluble in a cold solution of alum, while alizarine is not. When fixed on fabrics, its colours do not stand exposure to light as well as those of alizarine.

Professor Stokes, of Cambridge, has found a most elegant method of discovering and characterising mere traces of these colouring principles. So delicate is the test, that the colouring matter on 1 square inch of dyed fabric is sufficient to obtain the results. He treats the fabric with a solution of carbonate of soda, which dissolves the colouring matter. The solution is then introduced into a small tube, which is placed before a slit in the shutter of a dark room. The light which passes through is decomposed by a prism, when a spectrum is produced. The operator will observe that, when purpurine is taken, there are principally two black bands formed by the absorption of light in the green part of the spectrum, having between them a band of green light, whilst alizarine exhibits, on analysis, a band of absorption in the yellow, and another narrower one between the red and the orange.

Professor Schützenberger, by treating commercial purpurine successively with alcohol and benzine, unfolded it into four different substances, to which he assigns the following formulæ:—

- | | |
|---------------------|--|
| Alizarine | $C_{20}H_{12}O_6$. |
| 1. Purpuroxanthine | $C_{20}H_{12}O_6$, or $C_{20}H_{14}O_6$. |
| 2. Purpurine | $C_{20}H_{12}O_7$, or oxy-alizarine. |
| 3. Orange matter .. | $C_{20}H_{16}O_9$, or hydrate of purpurine. |
| 4. Pseudopurpurine | $C_{20}H_{12}O_9$, or oxy-purpurine. |

(To be continued).

CORRESPONDENCE.

ERNEST THEOPHRON CHAPMAN.

To the Editor of the Chemical News.

SIR,—Mr. E. T. Chapman, whose name is so well known to your readers and to the whole scientific world, was killed by an explosion in his laboratory at Ruebeland, in the Harz, on the 25th of June last. He appears to have been engaged of late in the manufacture of nitrate of methyl (called by the correspondent "salpetersäure methyl-æther"). Mr. Chapman, in one of his letters, describes the substance with which he was working as useful for blasting purposes, but remarkably difficult to explode, and indeed capable of being burnt like alcohol, without explosion.

The "bomb-proof" building in which Mr. Chapman and three workmen were engaged was blown up with a

terrific noise. All in the building were instantly killed. The surrounding buildings were injured, and ten other people were dangerously wounded. Nothing of course is known of the immediate cause of the explosion. Surely our experience is now sufficient for us to distrust explosives containing hydrogen and nitrogen oxides. And surely a "bomb-proof" building is the worst kind of building for storing explosives of any kind.

All who have the progress of chemistry sincerely at heart, will grieve that this man of great performance and boundless promise has been thus removed from us. Though Mr. Chapman was only twenty-six years of age, few living chemists have contributed more abundantly to organic chemistry, and his originality was as great as his skill and devotion.

Mr. Chapman had many opponents. No one worth his salt has not. But I do not think that there is one among even these who will not grieve at his death. A kinder, a gentler, a more generous heart never beat than the one which is now at rest beneath the pine woods of the Harz.—I am, &c.,

FREDERICK GUTHRIE.

PROPOSED ASSOCIATION OF MANUFACTURING CHEMISTS.

To the Editor of the Chemical News.

SIR,—I was very much interested in the letter of your correspondent "Frank" respecting the formation of an Association of Manufacturing Chemists. He will probably be gratified to hear, that in at least one of the great centres of chemical industry, the nucleus of such an association already exists. I refer to the "Tyne Social Chemical Society," a private association of the managers and chemists of nearly all the principal chemical works of Newcastle-on-Tyne and its neighbourhood. It has been established for the purpose of promoting a scientific and friendly intercourse among the practical chemists of the district. This is effected—first, by the reading and discussion of papers on manufacturing subjects; secondly, by conversations which are started on questions of practice arising from time to time, and which are frequently the means of eliciting the most valuable information.

We meet once a month in a very informal way, and except during the reading and discussion of the papers, our proceedings are carried on in little groups of twos and threes, discussing the last new thing in chlorine, the progress of A.'s new chambers, or B.'s break down, or C.'s new pumping engine.

It is surprising what an amount of solid information is exchanged at these meetings, the fact being that since almost every manufacture of the district is represented by one or more of its managers, you can get information upon any subject you want. Of course there is a certain etiquette observed in any process which is considered private, but these processes are so few that we have had but little difficulty on this head. We have discussed the manufacture of oil of vitriol in every minute detail, the Weldon process, the manufacture of soda-ash, kelp, ammonia, the economy of fuel, construction of pumps, boilers, and engines, incrustations, and a hundred other subjects, upon every one of which some one or more members could give the most useful practical information arising out of his own experience.

If the managers of other districts would form associations of this kind, I can assure them from my own experience and of the members of our society, that an incalculable amount of good would arise out of such genial association.

Hundreds and thousands of pounds might, as your correspondent observes, be saved by an intercourse of the managers of a district who would be most willing to communicate many of their experiences which they have no object in keeping to themselves.

That your correspondent may judge of the quality of our papers, I send you three in which he may probably feel interested, the first being the results of working the Weldon process at one of the largest manufactories on the Tyne; the second is on the manufacture of oil of vitriol and soda-ash by a thoroughly practical manager; and the third is an account of the construction of a chemical works erected in Ireland by the author of the paper, accompanied by a complete set of plans and sections, which have been photographed and distributed to the members.

Now, Sir, I contend that if societies like these were formed in various manufacturing districts, we could easily form an Association of Manufacturing Chemists, holding an annual gathering as "Frank" proposes.

I don't see why a commencement should not be made this autumn.

If any of your correspondents feel sufficient interest in the matter, I shall be happy to give them any further information about the above-named society, and I am sure the chemists of Newcastle will be most happy to greet their professional brethren here, if they will make this town the scene of the first meeting of the Association.—I am, &c.,

WILLIAM CROWDER,

Hon. Secretary Tyne Social Chemical Society,
Manager of Langdale's Chemical Manure
Co. (Limited), Newcastle-on-Tyne.

P.S.—As to the use of Coffey's still in the manufacture of ammonia, if your correspondent refers to vol. i., pages 180 and 181 of Muspratt's "Chemistry," he will find that it is an expired patent by Newton (1841), and there are some particulars which may prove useful to him.

ANALYSES OF MANURE.

To the Editor of the Chemical News.

SIR,—Annexed is copy of analysis, made by a public analyst, of a sample of dissolved bones taken from the stock of a well-known manufacturer. The sample is said to contain nitrogen equal to 3.57 of ammonia. No mention is made of the addition of ammoniacal salts. It appears to me that there is here an exceptionally high amount of ammonia for so-called "dissolved bones," especially as I understand there is no such thing as pure dissolved bone manure. If manufacturers do not dissolve some mineral phosphates along with the bones, they must use a large quantity of some article to dry them up after dissolving. But assuming that in this case the bones (pure) contained 4 per cent of ammonia, and that nothing was added except acid, either before or after dissolving, is it possible that the manure should contain 3.57 per cent of ammonia? If it cannot in the circumstances stated, then it is certain it cannot after the indispensable "dry" has been added.

Will any of your numerous readers be good enough to give an opinion on this point in an early issue.—I am, &c.,

June 14, 1872.

MANURE.

DENDRITIC SPOTS ON PAPER.

To the Editor of the Chemical News.

SIR,—Since I was unavoidably absent from the meeting of the Chemical Society held on Thursday, June 6, perhaps I may here be permitted to reply to Dr. Müller's remark upon my note on "Dendritic Spots on Paper," in which paper I show that the majority of such spots have an inorganic and not a vegetable origin, as was formerly supposed, and that they arise from small metallic particles present in, or adherent to, the surface of the paper.

Dr. Müller commented on the paper, and said "he had long ago observed these dendritic marks and knew them to be caused by portions of the bronze detached from the paper-making machinery." (*Vide* CHEMICAL NEWS, June 14, 1872).

Now, in 1869, when proceeding with the investigation of these spots, I wrote to Messrs. De la Rue and Co., asking them to kindly supply me with a quantity of paper containing such markings, of which I enclosed specimens, mentioning, I believe, in my letter the purpose for which I required it, and stating that I had found copper present in these dendritic spots, but had not at that time ascertained its state of combination, and therefore wished for a supply of material to enable me to do so.

In reply, I received a very courteous note from Dr. Müller, as follows:—

"110, Bunhill Row, E.C.,
July 5, 1869.

"Sir,—Your letter, dated 24th June, is to hand this morning. With regard to the spots you refer to, I would mention that this defect occurs sometimes with the paper, and it appears to me to be caused by being kept in a damp place, which condition favours the peculiar *fungoid growth* to which I ascribe these marks. I have none of this kind of paper at present at my disposal, but search is being made for it at my order, and should it be successful I shall be happy to forward you some for your investigation.—I am, Sir, your obedient servant,

"HUGO MÜLLER."

Hence it is evident that at that date Dr. Müller regarded the spots as vegetable growths, and has since modified his views in accordance with the communication which I made to him.

The dendritic markings mentioned by Messrs. Friswell and Spiller as occurring on prepared albumenised paper must have been noticed by everyone who has anything to do with such prepared paper; but then these markings bear no very near relation to the ordinary dendritic spots found on paper, for the former consist of metallic silver reduced by particles of some metal, such as iron, copper, &c., and the silver has crystallised out in an arborescent form, while the latter consist mainly of copper in combination with sulphur.—I am, &c.,

ARCHIBALD LIVERSIDGE.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Annalen der Chemie und Pharmacie, No. 8, 1872.

This number contains the following original papers and memoirs:—Hexyl-alcohol Obtained from Heracleum Oil, and on the Capronic Acid Prepared from it.—A. Franchimont and Th. Zincke.—After first briefly referring to Dr. Wohler's researches on this

subject, the authors state that they received about 200 grms. of the essential oil of an heracleum species (probably the *Heracleum giganteum*) grown in the Zoological Gardens in London, the oil being distilled there from the fruit of the plant alluded to. It appears that this oil consists of acetic acid octyl ether and butyric acid-hexyl ether, two isomeric ethers which can be separated from each other by fractional distillation. This memoir also treats on—Hexyl alcohol, $C_6H_{13}O$, a colourless liquid insoluble in water, exhibiting a strongly aromatic odour, boiling at 156.6° ; sp. gr. 0.819; on being oxidised this alcohol yields a fatty acid of the formula $C_{11}H_{21}O_2$. Hexyl-iodide, $C_6H_{13}I$, a liquid insoluble in water, boiling at 179.5° at 752.46 m.m. barom.; sp. gr. 1.4125. Hexyl-acetate, $C_8H_{17}O_2$. Hexyl-capronate, $C_{10}H_{21}O_2$. Capronic acid, $C_6H_{11}O_2$, an oily fluid, remaining liquid even at -6° , boiling at 205° . Capronic acid ethyl-ether, $C_8H_{17}O$, a pleasant smelling fluid: sp. gr. 0.876 at 17.5° , boiling at from 164.5° to 165.9° . Capronate of baryta— $Ba(C_6H_{11}O_2)_2 + H_2O$.

A large portion of this lengthy essay is devoted to the discussion of the question of the relation existing between the hexyl alcohol alluded to, its derivatives, and other bodies of similar composition.

Gallic Acid and Gallic Acid Ether.—H. Schiff.—The author refers to his former researches on this subject, and also to the researches of others, more particularly to those of Nachbaur, who stated that by treating gallic acid with chloracetyl there should be formed tetracetyl-gallic acid. According to the author this is not correct; on repeating the experiment the author obtained a body which, on being analysed, led to the formula—

that is to say triacetyl-gallic acid; with chlorbenzoyl (which corrodes glass rapidly) gallic acid yields tribenzoyl-gallic acid, a resin-like material, which becomes soft at 85° ; formula:—

Gallic acid ether; the formula of the lead salt of this body is—

Anhydrides of Salicylic Acid.—H. Schiff.—Notwithstanding the intrinsic value of this memoir, its contents, elucidated by a series of very lengthy and complex formulae, are not suited for abstraction.

Action of Phosphorus Oxychloride upon some Acids.—H. Schiff.—It appears that when the oxychloride alluded to acts upon acids, most of these, including even concentrated sulphuric acid, are decomposed, while metaphosphoric acid is formed; when the oxychloride is made to act upon phenolsulpho acid the result is the formation of anhydride of two molecules of the sulpho acid—

New Nitro Acid.—H. A. Kullhem.—The author gives a detailed account of the mode of preparation of dinitro-heptyl acid, the result of the very prolonged action of boiling nitric acid upon camphor. The acid alluded to, $C_7H_{11}(NO_2)_2O_4$, is a solid body, slightly soluble in water, crystalline, readily soluble in alcohol and ether; volatile at 100° , fusible at 215° , but with decomposition. The salts of this acid detonate when heated to 150° ; most of the salts are crystalline bodies.

Researches on the Inorganic Constituents of Blood.—A. Jariach.—The first instalment of an exhaustive monograph on this subject. This portion, elucidated by a large number of tabulated formulæ exhibiting results of experiments, treats on the blood of dogs. The temperature of the body of the dogs seemed to show that they were in a healthy condition.

Analysis of the Meteoric Iron of Ovikak in Greenland.—Dr. F. Wohler.—This is an exhaustive essay on the best and most expeditious methods of analysis of these minerals. The composition of the meteoric iron of Ovikak is per centually quoted as—Iron, 80.64; nickel, 1.19; cobalt, 0.47; phosphorus, 0.15; sulphur, 2.82; carbon, 3.69; oxygen, 11.09; total, 100.05.

Notice on Tyrosin.—L. Barth.—This brief paper contains some observations on the researches on tyrosin made by Beilstein, Kuhlberg, Glaser, Piria, and others. The author thinks that the synthetical composition of tyrosin has not yet been accomplished.

Bulletin de la Societe Chimique de Paris, No. 8, April 15, 1872.

The only original paper contained in this number treats on the—

Action of Iodide of Lead upon some Metallic Acetates.—D. Tommasi.—According to the reactions which take place between these two bodies, the acetates can be divided into three groups, viz.:—Such as combine with plumbic iodide (only acetate of potassa belongs to this group); acetates which, while reacting upon plumbic iodide, give rise to phenomena of double decomposition (diacetate of copper and acetate of mercury); acetates which act upon iodine plumbic simply as solvents (for instance, acetates of soda, ammonia, iron, &c.). The formula of the combination of plumbic iodide and acetate of potassa, also termed plumbic iodacetate-aceto-potassic, is—

or—

* O=16; C=12; Pb=207.

This memoir abounds with formulæ, while it also contains an account of the mode of preparation of the various salts and bodies described. Acetate of soda appears to be an excellent solvent for plumbic iodide.

Le Moniteur Scientifique Quesneville, No. 366, June, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

New View and Practical Observations on Typhus, Yellow Fever, Intermittent Marsh Fevers, and Peruvian Scorbut (Verrue Péruvienne).—Dr. M. C. Tasset.—A valuable contribution to the science of medicine, more especially in relation to the climate of Peru.

Crystallised Aconitine.—M. Duquesnel.—This essay relates to the history of the discovery of aconitine, and to the researches made on *Aconitum napellus*, by Steinacher (1808), Brandes (1819), Hesse (1833), von Planta Reichenau, Hottot, Grove, and others (the last-named author appears to have been the first to obtain crystallised aconitine). A lengthy account is given of the mode of preparing this substance, the formula of which is $C_{34}H_{40}NO_8$. From 0° to 100° , either in the presence or absence of water, heat has no action upon crystallised aconitine; it is almost insoluble in cold and boiling-water, and is partly decomposed and partly volatilised at 130° . It is soluble in alcohol, ether, benzine, and especially in chloroform; insoluble in glycerine, and light, as well as heavy, petroleum oils. Solutions of aconitine exhibit a feeble alkaline reaction to test-paper, while the alkaloid forms, with acids, salts which readily crystallise. Phosphoric acid, tannin, iodide of potassium, and the double iodide of potassium and mercury are the most sensitive chemical reagents for this alkaloid, the detection of which, according to the author, has to be aided by physiological experiments. A large part of this paper is devoted to the pharmaceutical preparations of aconite and aconitine.

On Fermentations: Examination of the Latest Discussions on this Subject as treated by Drs. J. von Liebig, Pasteur, and Fremy.—Dr. C. Blondeau.—Notwithstanding the intrinsic merits of this very exhaustive and lengthy memoir, its contents are not suited for abstraction. Incidentally, the author observes that Becher (1670) has been the first to observe some kind of analogy to exist between combustion and fermentation.

Note on the Analysis of Soaps.—F. Jean.—Reserved for full translation.

Les Mondes, June 27, 1872.

This number contains no original matter relating to chemistry, but we call attention to the following paper:—

Labours of the Italian Spectroscopic Society.—M. Tarry.—A condensed account of the observations made at the astronomical observatories of Italy in relation to the sun.

Revue Universelle des Mines, de la Métallurgie, des Travaux Publics, des Sciences et des Arts Appliquées à l'Industrie, Nos. 1 and 2 (double number), 1872.

In addition to several important original papers bearing upon engineering, mechanical, and metallurgical subjects, this number contains the following original paper relating to chemistry:—

Water of Hatray, near Spa, Belgium.—T. Kupferschlaeger.—The author states that, in a rather secluded locality opposite to the village of Sart, there constantly issues from the rocks an abundant quantity of water, which forms a rivulet at the base of the rocks and flows along the embankment of the railway, finally entering a large watercourse. It appears that this water, which hardly tinges blue litmus-paper red, is not rendered turbid by ferrocyanide of potassium, carbonate of ammonia, salts of baryta, or oxalate of ammonia; it contains only 0.05 grm. of solid matter to the litre, and is therefore well suited for domestic and industrial purposes. At present this water is turned to no use at all, while (especially for paper-making and other industrial applications) it is of great value, being far purer than most natural waters, excepting some met with in Sweden, Spain, and Switzerland.

La Revue Scientifique de la France et de l'Etranger, June 29, 1872.

This number contains no original papers relating to chemistry, but there is the concluding lecture on—

Animal Heat and the Influence of the Sympathetic Nervous System upon the Circulation of the Blood.—Dr. C. Bernard.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of Six dollars or £1 2s. 4d. per annum payable in advance.

THE CHEMICAL NEWS.

VOL. XXV. No. 659.

ON FERRO-TUNGSTINE,* A NEW AND INTERESTING MINERAL.

By HUGO TAMM.

SOME years since, a sample of a very remarkable mineral came to my hands. I was then unable to find out the place where it was originally discovered; and as I have not been any more successful since in my attempts to trace it to its source, I publish the result of an incomplete investigation of this substance, in order to call attention to it and rescue this really interesting mineral from oblivion.

The sample I had in my possession was so very small that this must be my excuse for not giving a fuller account of its composition and properties; but, with the description which I am going to give of it, it will be very easy to pick it out wherever it exists, whether along with other minerals, in mines, or among unexamined specimens in museums.

Ferro-tungstine is a dark steel-coloured, heavy, crystalline powder, formed of separate and distinct crystals, presenting exactly the appearance of crystallised silicium. Its specific gravity, which is considerable, is 12.5. It is a very hard substance, which can only be porphyrised with extreme difficulty, and it is almost impossible to reduce it to an amorphous powder; the powder obtained after a prolonged porphyrisation remaining still bright, like the powder of a crystalline metal or alloy, and crystalline.

Heated in the air at a low red heat, ferro-tungstine slowly oxidises, and is converted into a yellow powder of tungstic acid; and when it is thrown in fused nitre, it burns with brilliancy and is thoroughly attacked.

Ferro-tungstine is composed of—

Metallic tungsten	88.05
Metallic iron	5.60
Metallic manganese	0.15
Undetermined substance	6.20

100.00

I have no reason whatever to doubt the accuracy of the estimations of tungsten, iron, and manganese, which were repeated twice over with identical results, and I am quite at a loss to imagine what the undetermined substance may be; but this of course will easily be ascertained as soon as larger samples of the mineral are found.

It is not oxygen, for ferro-tungstine heated in a current of hydrogen does not lose any portion of its weight; nor does it when heated at a very high temperature in a carbon crucible. And yet the hypothesis of oxygen was very tempting, when we consider that, had the undetermined substance been oxygen, tungsten would have existed in the state of a new oxide—a suboxide.

The hypothesis of sulphur was equally fascinating, for in that case tungsten would exist as a new sulphuret—a subsulphuret; but ferro-tungstine does not contain a trace of sulphur.

It may be phosphorus, but it is not arsenic, and I do not believe that it is a metallic substance. What is it then?

* Mr. Tamm has done me the honour to propose that this mineral shall be called either "Crookesite" or "ferro-tungstine," and has left the decision to me. The name Crookesite having already been used by Nordenskjöld to designate a mineral containing a large quantity of thallium, I am unable to accept the honour proposed by Mr. Tamm, and have accordingly adopted the second name. At the same time, I would propose that the more appropriate name "Tammite" should be employed for this curious mineral as soon as the missing constituent is identified.—W. Crookes.

If I had been absolutely certain of the specific gravity of ferro-tungstine to the third decimal, I might easily have calculated the specific gravity of the undetermined substance, and I might easily afterwards have verified the indications given by specific gravity; but, although the specific gravity, 12.5, which I give is sufficiently correct for any practical purpose, I do not feel justified in forming any conclusions based upon it.

It is possible that the undetermined substance is hydrogen, or rather hydrogenium; in which case ferro-tungstine would really be a most remarkable mineral, being the first example of a native alloy of hydrogenium; but I had exhausted the small sample on which I operated when the thought struck me that it might be so.

It is possible, also, that nitrogen is the substance in question, or that it is a new element.

Lastly, it may be after all an analytical error, and there may be 6.2 per cent more tungsten than shown by the analysis, but I have strong doubts on that point.

But, as soon as ferro-tungstine is found anywhere, any obscure point of its history will soon be cleared by myself or by others.

CUTANEOUS ABSORPTION.

IN a recent note to the Paris Academy, M. Bernard writes as follows:—

I desire to submit to the Academy an account of experiments made in the Vincennes Asylum as to cutaneous absorption in baths of medicament vapour. In such an institution, among patients with various chronic affections, I am favourably situated for experimenting on this question on a large scale.

Reveil's memoir on the subject gives the facts which are known up to the present. "Absorption in the bath," he says, "only takes place in rare and exceptional circumstances; it is facilitated by washing the skin, continued rubbing, and by certain irritant and solvent substances."

The bath apparatus consisted of a furnace, a boiler, a chamber in which the steam coming from the boiler was charged with the substance to be applied, and a wooden cage, in which the patient was seated while enveloped in the vapour.

I used iodide of potassium in my experiments—(1) because it is not volatile; (2) because its presence in urine is easily determined by nitric acid and chloroform; (3) because, in seizing the iodine set at liberty by the nitric acid, the chloroform takes a rose colour varying in a marked way with quantity, and thus, by comparing with a graduated scale, one may determine pretty accurately, and without quantitative analysis, the quantity of iodide of potassium in the urine.

The skin of the subjects experimented on was intact, without wound or scratch. The urine was examined before the bath was taken, and the absence of iodine ascertained. By a respiratory tube, the patient breathed the external air through his mouth, the nostrils being pinched. A thick sheet of caoutchouc was bound by a T-bandage over the anus; the penis was sheathed in the same material; while the hands and feet were wrapped in cotton and gummed taffeta.

The subject was then placed in the cage, and subjected for thirty minutes to vapour from the mixing chamber, into which there had been put 20 grms. of iodide of potassium. The temperature in the cage was gradually raised to 45°; the skin of the subject became wet. He was then wrapped in a woollen covering and put in bed, when profuse perspiration took place. The urine analysed two hours after the bath gave a rose colour: some taken three hours after gave a much more lively colour; thus affording clear proof of the absorption of iodide of potassium through the skin, the only way it could have entered the system. Besides, if it had entered by pulmonary passages it would have been eliminated immediately after the bath.

These first experiments, then, prove the fact of cutaneous absorption.

In a second series I sought to determine to what temperature the air, mixed with medicament vapour, must be raised, in order to the absorption taking place.

A very sensitive thermometer was applied to the breast of the subject, and the temperature of the bath varied in the series of experiments from 30° to 38°, the time being, as before, thirty minutes. I only found the absorption take place when the temperature was 38° (or one degree above the temperature of the body). Indeed, the sebaceous matter in the cells of the epidermis only commences to dissolve at 38° when the skin is really wet; it is then that imbibition takes place, and consequently absorption. The iodide of potassium, conveyed mechanically by the vapour, penetrates the epidermis, whence it passes into the capillary blood system and the other organs.

Thus we understand how absorption does not generally take place in a water-bath. Owing to the density of the water, and its great specific heat, the temperature of such baths is usually not raised beyond 30° to 33°. Dr. Homolle remained in a bath at 34° or 35°; would he have been able to bear 38° or 39°? Besides, the liquid layer touching the skin is not constantly renewed, as in the vapour-bath.

I succeeded, however, in obtaining the cutaneous absorption at a temperature under that of the body, in the following way:—

The subject had first a simple vapour-bath, to destroy the sebaceous matter; his skin was washed and carefully dried, and he was replaced immediately in the cage, where he was exposed to the vapour of iodide of potassium for thirty minutes, the temperature of the bath varying, in several experiments of this kind, from 34° to 36°. Two hours after a bath at 34° the colouration of the urine was slightly rose; after a bath at 36° it was much more distinct.

M. Colin has described an experiment in which he allowed water charged with cyanide of potassium to fall for five hours' time on a horse's back. This caused the death of the animal; the sebaceous matter having been destroyed through percussion, and cutaneous absorption taking place.

In the sand-baths at Cette and Arcachon, which are found so efficacious for scrofulous affections, tumours, &c., what takes place? The temperature being considerably above that of the body (over 40°), the skin is wet, the sebaceous matter dissolves in the perspiration, and there follows absorption of the salts contained in the sand.

I have not been able to find free iodine in the urine; the use of nitric acid has always been necessary. Besides, iodine once introduced into the system soon forms various compounds.

In summing up his results, M. Bernard further mentions that the elimination of the salt, commencing two hours after the bath, increases in quantity till a meal is taken, after which it diminishes (probably because of the water received into the system), and then again increases. It ceases completely twenty-four hours after the bath, whatever the amount of the salt, the temperature, or the duration of the bath.

A. B. M.

ON THE CONSTITUTION OF MILK AND BLOOD.

By M. DUMAS.

DURING the most troubled years of the first French revolution, the old Academy of Sciences of Paris having been suppressed, its members none the less continued their patriotic co-operation in the labours required by the new necessities of the country. History has given them credit for this. It associates the names of the principal of them with those of the illustrious administrators and generals,

who then caused the integrity of the French soil to be respected.

The editors of the *Annales de Chimie*, who had been compelled to suspend their publication under the reign of Terror, on resuming it had the happy thought of collecting, in two volumes, all the memoirs or reports with which the Academicians had been charged. In running through these we appreciate at a glance the importance of the questions which were addressed to them, the insufficiency of the means at their command during those troublous times, and the merits of the practical solutions which they presented to the country, as the fruit of their previous studies, or of their improvised experiments.

Saltpetre, gunpowder, steel, weapons, gun-metal, potash, soda, soaps, paper, assignats, and many other objects implicated in the defence of the country, the working of its manufactures and the necessities of life, gave occasion to investigations and discoveries of which the factories have not yet forgotten the tradition.

The siege of Paris by the Prussian army could not, it was said, be sufficiently prolonged to raise any questions of the same kind; but nevertheless it has been necessary, as in the time of our fathers, to seek for nitrated earths, to produce gunpowder, to manufacture and work up steel, to obtain bronze and cast cannon; we have also been in want of paper, and of a great number of useful objects.

Considerable, although rapid, investigations have been accomplished; and it will be useful as well as just not to allow their memory to be lost. I have busied myself in collecting the materials for this publication, which I shall carry out as soon as circumstances will permit.

Among the privations which our forefathers did not know in their most cruel intensity, those which caused the most decided sufferings to the existing population, relate to the want of combustibles, which was rendered intolerable and most destructive by an exceptionally rigorous winter—to the scarcity of milk and eggs, the certain cause of the premature decease of a great number of young children—and, finally, to the exhaustion of the supplies of corn, flour, and meat, which, rendering the capitulation of Paris inevitable, marked the precise day for it.

Three questions, which have occupied the mind of every man curious to foresee the future of science, were thus incessantly presented to the meditation of the scientific men shut up in Paris, not as far-away dreams in which the imagination delights and disports itself, but as the despairing prayers of a people in utter extremity:—

1. To obtain available heat, without combustibles;
2. To re-construct food with mineral materials, without the co-operation of life;
3. To reproduce, at least, the essential food of man with non-alimentary organic materials.

Man, in warming himself by means of combustibles furnished either by the existing vegetation, or by the remains of the ancient vegetation of the globe, and in nourishing himself by means of products obtained from plants and animals, demands everything from life; but could he dispense with life in obtaining his combustible and his nutriment? Would the forces of science alone suffice to assure to him, in this urgent need, those satisfactions which he could no longer demand from the forces of living nature?

This was the question. If put in a time of peace and in the midst of abundance, it would probably have received more than one response in the affirmative. The progress of the physical sciences has been so brilliant! One is so much disposed to exaggerate their power! Electricity opens up such seductive perspectives! Synthesis has produced so many marvels in the hands of chemists!

If the necessity had not been so pressing, so that the question might have been raised as a philosophical thesis, and we could have said to the physicists and chemists, could you not, if it were necessary, furnish man with heat and food without having recourse to plants and animals? how many, without saying *yes*, would at least have answered with one of those smiles which do not say *no*.

But in a crisis where it was necessary to realise immediately what would have been left to hope, people showed reserve; radical solutions were adjourned, and there was no question either of heating Paris without combustibles, or of feeding it without organic aliments.

But could organic materials usually disdained be converted into aliments, so as to replace, by means of clever combinations, those natural products which could no longer be procured?

It is not my design to notice what viands were served at table, or what resources we were led to seek in the blood and offal of the slaughter-houses which are usually thrown away, the bones, feet, and even the skins of the cattle slaughtered. Nor will I examine how the butter and lard, which were speedily exhausted, were replaced. Of these improvised arts some have disappeared with the circumstances which gave them birth, whilst others have left some useful teachings.

I shall treat only of a special question, the solution of which involved certain principles which it seems to me to be important to guard. Was it not possible to come to the assistance of new-born children by replacing the milk, which could no longer be got, by some saccharine emulsion? In this case there was no question of creative chemistry, but only of culinary chemistry. Recipes were not wanting, all reproducing an albuminous liquid, sugar, and an emulsion of a fatty body.

As a provisional succedaneum this artificial milk deserved to be welcomed. But sometimes there was such a conviction in the authors of these propositions, that one was forced to dread for the future the effects of their faith. This was of a nature to make too many proselytes, to the great injury of the children at nurse, and the great profit of the dealers in milk. How could the latter have the least scruple when they were taught to manufacture an emulsion which they saw recommended to the consumers, and even to mothers, as the real equivalent of milk?

The services rendered by concentrated milk during the siege were too important to render any excuse necessary in the country which produces it, when we insist upon the preference always due to natural milk, as also upon the characters which at present do not permit us to confound any artificial milky liquid whatever with the truly secreted product.

Natural milk forms a liquid containing salts, sugar, casein in solution, and fatty globules in suspension. Let us first see whether we can imitate these fatty globules by dividing or making an emulsion of an oily or fatty matter in a viscous liquid.

I believe that I experimentally demonstrated the contrary some years ago, by showing that the globules of fatty matter of milk are protected from certain physical or chemical reactions by a true membranous envelope. Admitted by some, and disputed by others, the existence of this membrane seeming to me to be real and proven, there could be no question, in my opinion, about confounding an artificial emulsion with naked fatty globules with milk from the mammae, presenting fatty globules enveloped by a membrane, true free cells, filled with butter, analogous to the agglutinated cells of adipose tissues.

The existence of this membrane may be proved by two chemical experiments.

The first depends upon the property possessed by sulphuric ether of dissolving fatty matters and collecting together those which are suspended in liquids, provided that they are free. Now if, after shaking together in a tube fresh milk and ether, they are left to rest, the ether floats on the surface without having dissolved anything, and the milk resumes its place below the ether without having lost anything of its appearance, or yielded any of its buttery matter.

But when subjected beforehand to the action of acetic acid, which is able to dissolve the envelopes of its fatty globules, milk, when shaken up with ether, loses its opacity, and yields its butter to that liquid, in which it may be found.

An inverse test leads to the same conclusions. A neutral salt, such as sulphate of soda, added to milk, enables us to filter it, and to retain upon the filter the globules of butter, whilst the serosity flows off perfectly limpid and clear. If the washings with saline water be continued, these globules may be freed from all the soluble products of the serum. Now if the butter consisted of simple fatty globules, there would then remain with no trace of albuminous or caseous matter. But whatever care may be taken to prolong the washings, we always find with the fatty matter such a proportion of albumenised substance that there can be no doubt that it has remained there in the form of those envelopes or cells which constitute the globules of butter.

The microscope, moreover, shows plainly the constitution of the globules of butter, and reveals the constant presence of the envelopes. It is sufficient to crush the globules of milk by means of the compressor, to obtain a conviction that, after the spreading of the fatty matter, the butter-cell still retains its form and outline, thus showing that the contents and the container have each their distinct existence.

For these reasons, and for many others (for no conscientious chemist can assert that the analysis of milk has made known all the products necessary to life which that aliment contains), we must renounce, for the present, the pretension to make milk, and especially abstain from assimilating any emulsions to this product.

Besides we cannot have too much reserve where we have to pronounce upon the identity of two products, one natural, the other artificial, if they are not crystallisable or volatile—that is to say, definite. We can never affirm that we have reproduced a mineral water, or sea-water for example. When manure for plants, or aliments for man and animals are in question, is not the same reserve still more imperative?

These indefinite natural mixtures contain substances which the coarsest analysis discovers, with others less strongly characterised or less abundant, which are only revealed by delicate chemistry, and others again, and perhaps the most essential, which still escape us, either because they exist in infinitesimal proportions, or because they belong to the category of bodies which have not hitherto been distinguished from other chemical species.

It is therefore always prudent to abstain from pronouncing upon the identity of these indefinite mixtures employed in the sustenance of life, in which the smallest and most insignificant traces of matters may prove to be not only efficacious, but even indispensable. In proportion as science extends her domain, we are sure to see the demonstrations of the appropriateness of this reserve multiplied.

Among the fine investigations executed in France by those who have continued the labours which occupied the life of the illustrious Théodore de Saussure, the important thesis of M. Raulin upon the vegetation of *Aspergillus niger* will always be placed in the foremost rank. All the conditions of the life of this Mucedinean have been so well determined by that author that it may be cultivated with precision in a soil formed of definite chemical species, as if we had to do with the formation of a compound; and the soil once sown, we may follow the transformation or the employment of each of the elements necessary to its life, just as if we had to do with the development of an ordinary chemical equation.

Now, who could have foreseen that the *Aspergillus niger*, which has just made its appearance, for example, upon a slice of lemon, exposed to the air, required for the fulness of its existence traces of oxide of zinc? How, after this, can we doubt, in the case of plants of a higher order and especially of animals, that, besides their coarsely appreciable aliments, they require also traces of many other aliments, more delicately used but not less necessary?

Milk has often been compared to eggs, both from a chemical and a physiological point of view. Their mission is equally to furnish the young animal with the

nourishment of its earliest age; and they have as a common character that they present in union a fatty matter, an albumenoid substance, a saccharine or amylaceous matter, and salts.

But the egg possesses a vitality, an organisation, of which chemistry furnishes no evidence, and which the most minute anatomy would be powerless to reveal. If fecundation had not rendered manifest, by the rapid phenomena of segmentation which take place in it, that the mass of the yolk of an egg is endowed with life, and that it obeys the impulsion of the living germ which takes possession of it, we should still be ignorant that the yolk of the egg is not a mere emulsion of inert fatty matter.

Is not milk in the same case? One is led to think so when we see that the yolk of the egg and milk have the same destination and the same configuration, and that, if the yolk obeys the action of the germ which is nourished by it, milk, for its part, proves to be singularly ready to receive and nourish germs of more than one kind, which, on reaching it, become developed and live at its expense.

The power of synthesis of organic chemistry in particular, and that of chemistry in general, have therefore their limits. The siege of Paris will have proved that we have no pretension to make bread or meat from their elements, and that we must still leave to nature the mission of producing milk. If some illusions upon this point have found their way into the minds of persons ill-informed as to the true state of science; they are due to the dangerous play of words to which the expressions *organic chemistry* and *organic substances* lend themselves, when applied, as these are, indifferently, to definite compounds, such as alcohol or citric acid, which are unfitted for life, and to indefinite tissues, the seat of life.

The former (foreign to life, and true chemical species) are the only ones that synthesis has reproduced. The latter, which can be formed only under the impulse of a living germ, and which receive, preserve, and transfer the forces of life, are not definite species; the synthesis of the laboratories does not reach them. The only synthesis which has hitherto been observed in the case of the chemical materials which constitute living tissues, is that determined in brute matter by the presence and impulse of the living germ itself.

All those chemical syntheses, otherwise so worthy of interest, which have been indicated as reproducing organic matters, have therefore in reality reproduced only matters, unfitted for life—that is to say, mineral matters. Thus of every living matter or matter that has lived, we must still, whether we speak as chemists or physiologists, say what was said of it formerly: *omne vivum ex ovo*—that which is not life has brought nothing to life.

With regard to the constitution of milk, the phenomena presented by the clarifying of butter have been sometimes employed either to demonstrate or to dispute the existence of the membranes which envelope the butyrous globules; I cannot at present regard these phenomena as having any value in this respect.

It has been said, for example, that the separation of butter was the result of the formation of lactic acid arising from the action of the air, favoured by churning. Numerous experiments effected in my laboratory upon a practical scale have shown that butter separates equally promptly, and at least equally abundantly, from a milk to which a large amount of bicarbonate of soda has been added, as from natural milk. The alkaline reaction of the former, which is maintained during the operation and after its completion, has no influence either upon its duration or its result. The proportion of butter, far from being diminished, seems even to have been increased by it.

The formation of lactic acid is therefore not necessary for the separation of butter, which appears to me to be due to purely mechanical causes. Such, at least, is the feeling that one experiences on examining by the microscope milk submitted to churning whilst the operation is going on. The first test-drops present nothing peculiar; the globules of butter retain their form, dimensions, and

aspect. Soon we see appear irregular butyrous islands in the midst of globules remaining unaltered. These islands of butter increase in number and extent in proportion as the operation proceeds. They form a snowball, uniting with each other and becoming agglomerated, so as to constitute at last the mass of butter which is the object of the operation.

The agglomeration of the butyrous globules into a block of butter would be a true regelation if there were no membrane surrounding them. The existence of this compels us to admit that it must be broken, and that this is the object of the repeated shocks which we make the liquid undergo, in order that the diffused butter may unite with the fatty parcels and agglomerations which it meets with on its road.

If it is true that the separation of butter is a purely mechanical phenomenon, it is not the less so, as I shall hereafter show, because chemistry can give rules to render this operation more rapid and more efficacious, and to produce from it a better clarified and less alterable butter.

I conclude this communication with some details upon phenomena of another nature, towards which the hygienic situation of the inhabitants of besieged Paris turned one's thoughts only too naturally. What took place in the tissues of this population deprived of fresh vegetables, fruits, milk, fish, and fresh meat? What changes did the blood undergo under the influence of this diet? and how must they manifest themselves?

Some years ago I had prepared some experiments, the object of which was to ascertain whether exchanges by exosmosis and endosmosis take place between the internal liquids contained in the globules of the blood and the liquids of the serum. If these exchanges were easy and rapid, their existence might be ascertained. To demonstrate them would be to ascertain by what means the constitution of the globules of the blood may be altered and vitiated, re-established, or regenerated.

I never completed these experiments; but I have often depended upon the views which guided me, in order to make the auditors in my courses at the Faculty of Medicine understand how certain alterations of the blood might be interpreted.

It is necessary, perhaps, to explain what stopped me.

Nothing is easier than to compare the serum and globules of a normal blood with the serum and globules of the same blood, modified by the intervention of a substance capable of changing the direction or the intensity of the powers of endosmosis between the globules and the serum.

In the blood of a living animal the globules suspended in the liquid may absorb or lose some of their elements, if we succeed in changing the constitution of the serum; but how long will the phenomenon last? If the substance added be mischievous it will be eliminated; the veins on their part will absorb liquids destined to re-establish the equilibrium, and the experiment will soon be so altered that the little differences that we have to measure will disappear, vanishing before great complications.

On the contrary, if we withdraw the blood from the body of the animal and divide it into two parts of equal weight, one destined to furnish the term of comparison, and the other to receive the substances modificative of the power of endosmosis, coagulation and what I have called the asphyxia and death of the globules will soon do away with any hope of arriving at certain results.

It was therefore necessary to receive the blood into a vessel, to oppose its coagulation, and to replace towards it the action both of the heart and lungs—that is to say, to keep the blood in movement and to present it in a very divided state to the action of oxygen or of the air. I arranged an apparatus which fulfilled these conditions, and allowed one to ascertain how alcohol, neutral salts of soda or potash, sugar &c., act when added to the serum, and how the interior liquids contained in the globules may become modified under their influence either in quantity or in nature.

While I followed out these views, preoccupied by the

evident invasion of scurvy in the general state of health of the inhabitants of Paris towards the close of the siege, and whilst I sought to make up by applicable means for the absence of all fresh vegetables and of all fruit in their habitual diet, a foreign doctor, Dr. J. Sinclair, by following out the ideas which he had heard me teach upon this subject, was led to seek in them the explanation of the first symptoms of alcoholisms, a state which he designates by the name of dysomania.

Just as scurvy would have as its primary cause an impoverishment of the serum in potash-salts and a surcharge of salts of soda (which favours the exosmose of the potash of the globules and consequently their destruction), so alcoholism would have as its starting-point the presence of the alcohol in the serum of the blood and its effects on the globules.

Alcohol added to the serum causes a movement of exosmose from the interior of the globules to the serum. The globules lose a part of their constituent liquids; and this alteration, which brings on others, is no doubt reproduced in the cells of the various tissues which are bathed by alcoholised liquids.

What it is now my intention to prove is, that in the blood in particular, and in every living organism of analogous constitution (that is to say, formed by cells or utricles filled with a liquid and floating in or bathed by a liquid), it is sufficient to alter, even slightly, the chemical composition of the exterior liquid to cause that of the interior liquid to become modified by endosmose or exosmose.

I propose to follow out the development and application of this principle, either to demonstrate the effects produced by the action of common salt, alcohol, &c., upon the blood, or to show how rapid is that of some agents, of which I have already examined the action, upon the constitution of the globules.

STEAM-BOILER WATERS AND INCRUSTATIONS.*

By Dr. JOSEPH G. ROGERS, of Madison, Ind.

ALL natural waters contain more or less mineral matter. This is acquired by contact with the earth's surface, and by percolation through its soil and rocks. It consists principally of carbonates of lime and magnesia, sulphate of lime, and chloride of sodium, in solution, and clay, sand, and vegetable matter, in suspension. The many other saline ingredients found in various waters exist in very small proportions, are generally very soluble, and therefore have no relation to the utility of waters in boilers. Of the above-mentioned salts, the carbonates of lime and magnesia are only soluble when the water contains free carbonic acid—consequently the waters of rivers, lakes, &c., contain them in less quantities than those of wells, springs, and creeks, owing to the precipitation caused by the spontaneous evolution of the solvent on exposure to air, heat, and light. Our American rivers contain from 2 to 6 grains of saline matter in the gallon, in solution, and a varying quantity in suspension, generally exceeding 10 grains. Well and spring waters hold but little in suspension but a quantity of the dissolved salts, varying from 10 to 650 grains in the gallon. When such water is boiled the carbonic acid is driven off, and the carbonates, deprived of their solvent, are rapidly precipitated in a finely crystallised form, tenaciously adherent to whatever they may first fall upon. Sulphate of lime requires 500 parts of water for its solution, and as the water evaporates supersaturation occurs, and the salt is precipitated in the same form and with the same adherent quality as the carbonates. Chloride of sodium and all

the other more soluble salts are precipitated by the same process of supersaturation, but, owing to their greater solubility, much more evaporation is required. All suspended matter gradually tends to subside. This combined deposit, of which the carbonate of lime usually forms the greater part, remains adherent to the inner surface of the boiler, undisturbed by the force of the boiling currents. Gradually accumulating, it becomes harder and thicker, till it is as dense as porcelain, though tougher, and at length may obtain such a thickness as to prevent the proper heating of the water by any fire that can be placed in the furnace. The high heats, sometimes necessary to heat water through thick scale, will sometimes convert the scale into absolute glass by combining the sand with the alkaline salts composing it. The evil effects of the scale are due to the fact that it is relatively a non-conductor of heat. Its conducting power compared with that of iron is as 1 to 37.5. Consequently more fuel is required to heat water in an incrustated boiler than in the same boiler if clean. A scale $\frac{1}{8}$ th inch thick will require the extra expenditure of 15 per cent more fuel. This ratio increases as the scale is thicker. Thus when it is $\frac{1}{4}$ inch, 60 per cent more fuel is needed; $\frac{1}{2}$ inch, 150 per cent, &c. Abstractly then, to raise water in a boiler to any given heat, the fire-surface of that boiler must be heated to a temperature according with the thickness of the incrustation in an increasing ratio. To illustrate—to raise steam to a pressure of 90 lbs., the water must be heated to about 320° F. In a clean boiler of $\frac{1}{4}$ inch iron this may be done by heating the external surface of the shell to about 325°. If $\frac{1}{4}$ inch of scale intervenes between the shell and the water, such is its non-conduction that it will be necessary to heat the fire-surface to about 700°, almost low red-heat. Now the higher the temperature at which iron is kept, the more rapidly it oxidises, and at any heat above 600° it very soon becomes granular and brittle, and is liable to bulge, crack, or otherwise give way to the internal pressure. This condition predisposes the boiler to explosions, and makes necessary expensive repairs. Again, it is readily seen that the presence of scale renders slower and more difficult the raising, maintaining, and lowering of steam.

To obviate the evils arising from incrustation, many methods have been devised to prevent and remove it. For this purpose picking, scraping, cleaning, &c., are very generally resorted to. Such is its toughness and tenacity, however, that this only partially succeeds, and is more-over expensive in time and money, since it is generally necessary to lose a working day in the operation. Various mechanical contrivances have been introduced, intended to intercept the precipitated saline matter from the supply water on its passage through the heating apparatus. They consist essentially of a series of obstructions to the flow of the water. After it has been heated almost to boiling by the exhaust steam, the carbonates are precipitated, and subside upon the shelves, straw, and other obstructions, over which the water flows. This plan, however, only partially fulfils the purpose, since it only intercepts a portion of the carbonates and suspended matter. The soluble salts all pass on into the boiler, and a great portion of the dissolved carbonates also, which cannot be precipitated during the short passage through the heater. The scales form more slowly, but as surely. It is impossible to make such contrivances completely efficacious. No mechanical arrangement will suffice. To chemistry alone must we look for the desired means. For a long time simple chemical means have been used in an empirical way with some success. The *modus operandi* of some of these I will notice. Starchy matters—such as Indian corn, potatoes, oil-cake, &c.—prevent scale only by enveloping the precipitates with gelatinous matter, thus lessening their weight, causing them to float, and obviating their agglutination into solid masses. This application, however, tends to cause foaming or frothing of the water, making it impossible to determine the quantity in the boiler, and hence is objectionable.

* Abstract of a paper read before the American Association for the Advancement of Science at Indianapolis, 1871.

Molasses, fruits, cider, slops, vinegar, cane-juice, and a variety of other things, containing more or less acetic acid, placed in the boiler, convert the carbonates into soluble acetates. The sulphate of lime remains unaltered, however, and the iron being as much open to the attacks of the acid as the saline matter, the boiler is slowly, but surely, damaged.

Oak, hemlock, and other barks and woods operate by means of the tannic acid therein. Various extracts, such as catechu, logwood, &c., very rich in tannin, are also used. Tannic acid decomposes the carbonates, but, unlike the acetates, the resulting tannates are insoluble. Their specific gravity, however, is low; they float in the currents of ebullition, and, having no tendency to adhere, do not agglutinate into a mass, and cannot form a scale. The sulphates and chlorides are not acted upon at all by the tannic acid, and will incrustate notwithstanding its presence. Tannin, as offered in the above-named agents, is left free to act upon the iron, and will, after a time, exhibit its damaging effects on the boiler.

The fixed alkalis are much used for this purpose, in the various forms of lye, ashes, carbonate of soda, caustic soda, potash, &c. These agents decompose the sulphate of lime, sulphate of soda or potash and carbonate of lime being the results. The first is held in solution, the latter is precipitated, but in larger crystals, which do not form so refractory a scale as ordinarily. The carbonates of lime and magnesia are also precipitated by these agents, the free carbonic acid being taken to form carbonates or bicarbonates of soda or potash; the chlorides are not affected. This method simply modifies the form of the precipitate, and consequently the quality of the scale, without affording any means for its prevention, and therefore deserves but little attention. Ammonia and its carbonate have a precisely similar action, and the same objection stands against them. These alkalis have no chemical action on the boiler, but rather tend to preserve it, inasmuch as they prevent the free carbonic acid from combining with the insoluble crust of oxide of iron (formed by contact with the water) to form a soluble carbonate of iron, which, being dissolved away from the iron, would leave a surface constantly exposed to fresh action. Chloride of ammonium is another means employed. This has its action only on the carbonates of lime and magnesia. The reaction produces carbonate of ammonia, which, being volatile, passes off with the steam, and chlorides of calcium and magnesium, both very soluble. This is an efficient way of removing old scale. Its only objection is the ammoniacal odour of the escaped steam.

The foregoing are methods in which a single agent is used. They are frequently combined with a view of obviating the mentioned objections. Starch, tannin, and soda constitute the basis of most of these combinations. Crude petroleum is also used with reported partial success. The rationale of its action is not well understood, owing to the complexity of its chemical constitution. There are many proprietary compounds at present in use composed essentially of these elements, generally, however, with the addition of other things, introduced for the purpose of disguising their composition. Besides these, many other preparations are before the public which have been patented, all having a general resemblance, inasmuch as tannin, starch, and soda are the principal ingredients, in some form. Gum catechu is most generally the tannin-bearing body; sal soda, the alkali; and flax-seed, oil-seed cake, bran, or coarse flour the starchy element. In most of those which I have examined these very useful agents have been simply mixed empirically, without regard to chemical laws, and they generally contain more or less free tannic acid, and a considerable amount of inert, insoluble vegetable matter, which tends to produce foaming, besides being useless. Besides these methods, in which the chemical agents are introduced directly into the boiler, others have been devised, in which the waters are depurated, by chemical means, before entrance into the boiler. Clark's process consists in the precipitation of the car-

bonates with milk of lime, the free carbonic acid being taken up; the sulphate of lime remains in solution. Another method, proposed by myself, consists in converting the earthy carbonates into soluble chlorides by hydrochloric acid, and neutralising the excess of acid by filtration through carbonate of baryta (witherite) in coarse powder. The soluble chloride of barium thus formed decomposes the sulphate of lime, chloride of calcium being kept in solution, and the sulphate of baryta being deposited insoluble. This method recommends itself for railway water stations, on account of its cheapness and simplicity.

Oxalic acid may be used very efficiently for the complete precipitation of all the lime salts as insoluble oxalates, but the expense might be a bar to its use. Tannic and acetic acids, the excess being properly neutralised by carbonate of soda, may also be used for tank depuration.

These tank methods, however, cannot influence to any great extent the scale already formed; and as the removal of this is as needful as its prevention, it is palpable that that method is best for general application which attains the complete removal, as well as prevention, by chemical means operating inside the boiler.

Having this end in view, the writer has proposed two processes: one consists simply in the introduction into the boiler of a sufficient quantity of the oxalate of soda to cause the immediate decomposition of the scale-forming salts as they enter the boiler, converting them into insoluble oxalates, which are precipitated as a mushy sediment, which has no tendency to form scale, and which may be blown out from the mud-receiver, or otherwise voided. In the other process tannate of soda is the agent, kept constantly present in the boiler in solution; it decomposes the carbonates of lime and magnesia as they enter, tannates being precipitated in a light, flocculent, amorphous form, so that they do not subside at all in the boiler, but are retained in suspension by the boiling currents until they find their way into the same receiver, when they settle into a loose, mushy mass, which may be easily blown out from time to time. The carbonate of soda formed in the reaction is retained in solution, becoming a bicarbonate by appropriation of the free carbonic acid in the water. This decomposes the sulphate of lime, the resulting sulphate of soda being retained in solution, and the carbonate of lime being acted upon by fresh portions of the tannate of soda as above. The constant presence of the alkali protects the iron from all action, either of the carbonic or tannic acids. The same reactions take place between the tannate of soda and the already existing scale with like results, but more slowly, some weeks being generally required, in practice, in removing the deposit, if it exists in any considerable quantity.

Portions of scale are detached, from time to time, which may be removed at the usual cleanings, which should be made at short intervals, when possible, until the boiler is entirely clear of all incrustation, after which this will not be necessary. Extensive practical trial of this process for two years has demonstrated its utility for all varieties of boilers. It is economical, easy of application, and generally adaptable. It may be used in marine boilers as well as those using fresh water, since the marine scale is almost identical with that formed in boilers using ordinary waters, consisting almost entirely of the carbonates of lime and magnesia and sulphate of lime. The chloride of sodium forms a mushy deposit, but is only incorporated in the scale to a slight extent.

University of London.—The following is a list of the candidates who have passed the recent D.Sc. Examination:—*Branch VI. Electricity.*—Alexander Muirhead, University College. *Branch IX. Animal Physiology.*—Henry Newell Martin, M.B., Christ's Cambr. and University.

ON A RELATION BETWEEN THE CHEMICAL
GROUPING OF CERTAIN ELEMENTS,
AND THE
QUANTITIES IN WHICH THEY EXIST UPON
THE EARTH'S SURFACE.

By JOHN A. R. NEWLANDS, F.C.S.

If a list be made of the fourteen principal elements which occur on the earth's surface (including the ocean and the atmosphere) in the largest quantities, which are also most widely distributed, and which appear essential to vegetable or animal life, it will be observed that they comprise two representatives of each of the chief chemical groups. Thus we have—

1. Hydrogen and chlorine.
2. Sodium and potassium.
3. Magnesium and calcium.
4. Aluminium and iron.
5. Carbon and silicon.
6. Nitrogen and phosphorus.
7. Oxygen and sulphur.

Hydrogen and chlorine are here classed together on account of their mutual replaceability, with but slight change of properties, in many chemical compounds, such as trichloroacetic acid, &c. The position, too, of hydrogen in the list of elements, when arranged in the order of atomic weights, indicates that it is really the lowest member of the chlorine group.

ON DYES AND DYE-STUFFS OTHER THAN
ANILINE.*

By Dr. F. GRACE CALVERT, F.R.S.

(Continued from p. 10).

I SHALL now call your attention to a very remarkable discovery, recently made by the late Professor Bolley, viz., the conversion of purpurine into alizarine. If purpurine is heated in the atmosphere, as stated above, it is nearly all sublimed, leaving only a small amount of carbonaceous residue, but if heated in sealed tubes, at a temperature of 400°, it forms a carbonaceous mass, from which water extracts alizarine. Under the influence of the high temperature, the purpurine loses an equivalent of oxygen, and is converted into alizarine. This reaction appears to confirm the opinion of M. Decaisne, that the madder plant contains only one colour-giving principle, which under the oxidising influence of the atmosphere becomes converted, first, into alizarine, then purpurine, and afterwards into the still more highly oxidised compounds.

The difficulty and expense experienced by calico-printers in brightening their colours, and obtaining pure whites in madder-dyed goods, attracted many years ago the attention of scientific and practical men, and any process by which these difficulties might be overcome was anxiously looked for. The discovery of MM. Robiquet and Collins, that the colour-giving principle was not destroyed by sulphuric acid, was the step in that direction, and led M. E. Schwartz to observe that the carbonaceous mass of Robiquet, if carefully washed and neutralised, could be used as a dye-stuff. MM. Lagier and Thomas improved upon this, and introduced, in 1839, an article which is now extensively used by calico-printers and named garancine, and now is prepared as follows:—Madder, either unwashed, or, better still, washed with cold water, is mixed with one-third of its weight of sulphuric acid which has been previously diluted with water till it marks 10° Twaddle; it is then boiled for

four or five hours, and the mixture run on to woollen filters, and washed till only a mere trace of acid remains. It is then either removed or washed once with a very weak solution of carbonate of soda, submitted to hydraulic pressure, and then introduced into drying stoves. One hundred parts of madder yield from 34 to 37 of garancine. Garancine is a fine powder, of a light brown colour, and has a dyeing power four times as great as the original madder. It does not give as good blacks as madder, nor are its purple, red, and pink so fast, but its purple is brighter, and the whites are obtained pure without soaping, it being only necessary to substitute a slight clearing liquor, composed of an alkaline hypochlorite of soda, to which is added a small portion of sulphate of zinc.

In 1852, Messrs. Pinckoff and Schunck effected an improvement in the manufacture of garancine, their product being known in England under the name of commercial alizarine; but on the Continent it is better known as *Pincoffine*. Their process consists in submitting ordinary garancine to the action of high pressure steam of a temperature of 300° F., which, whilst it does not act on the alizarine contained in the garancine, destroys two other colouring matters which are present. These Dr. Schunck has isolated and examined, and named *Rubertine* and *Rerantine*. They are of a peculiar resinous nature, and spoil both the whites and the purples, which are fixed along with alizarine in the dyeing process. The employment of commercial alizarine is especially advantageous in the production of purples, which are faster and more brilliant than those produced by ordinary garancine. The cloth also does not require either soaping or cleansing.

M. Pernod, has, within the last two or three years, introduced a madder extract, which is at the present time extensively used in Lancashire as a topical colour. This term is applied to a colour which is printed on a fabric, and afterwards fixed by steaming. By this method bright and fast colours are introduced in printed goods, producing much more effective designs than could be effected if the goods had to pass through a dye-beck and afterwards be washed with large quantities of water. Some splendid specimens of this class of printing were to be seen at the Universal Exhibition, 1867.

To prepare the extract, garancine is lixiviated till completely exhausted, with a nearly boiling solution of sulphuric acid, containing five parts of acid to a thousand of water. On cooling, an orange-red precipitate falls to the bottom of the vessel, which, when collected and thoroughly washed, constitutes an extract ready for use. The products of M. Leitenberger and Messrs. Schaeffer and Lauth may be substituted for this extract.

As the employment of these extracts is the most important improvement recently introduced into calico printing, I will give the three following recipes for their application:—To produce dark red, take 8 lbs. of extract of madder, 4 lbs. acetic acid, and 1½ lbs. starch. Boil these in an earthenware vessel, and when cold add to six measures of the above one of acetate of alumina and a very small quantity of Gallipoli oil, say one per cent. For a pale red, take 4 lbs. of extract of madder, 2 lbs. of acetic acid, 10 quarts of gum Senegal water, and 1 pint of acetate of alumina. To obtain a purple, take 1 pint of extract of madder, half pint of acetic acid, half pint of water, and 3 ozs. starch; boil, and when the mixture is cool, 5 ozs. measure of acetate iron of 24° Twaddle, and 5 ozs. of water. To produce a chocolate, proceed as in the last recipe, substituting acetate of chrome for the acetate of iron.

The above mixtures are printed on cloth by means of engraved copper rollers, and are then dried and submitted to dry high-pressure steam for one or two hours, when the colours have become fixed on the fabric. After being slightly soaped, to remove all excess of colour, the prints are stiffened, and ready for the market.

Although I have now concluded my lecture on madder as a dye-stuff, and have already exceeded the time allotted

* The Cantor Lectures, delivered before the Society of Arts. Revised and communicated by the Author.

to me, I hope you will allow me a few minutes more, to enable me to give an outline of the processes by which madder styles are produced, the more so as there may be some persons present who are not aware how madder and garancine prints, now manufactured in such enormous quantities and in such general use, are produced.

To effect this, the ordinary white calico, as sold in shops, is not sufficiently deprived of its impurities to be employed in madder or garancine styles; it has therefore to undergo further bleaching operations. The calico so extra bleached is then printed by means of copper rollers, on which the pattern to be produced is engraved. This roller leaves on the calico a red, purple, or chocolate mordant; that is for red, a sulpho-acetate of alumina, or red mordant; for purples, violets, and blacks, an impure acetate of protoxide of iron, known in the trade as pyrolignite of iron, or black liquor; and for chocolates a mixture of these two mordants.

After this operation the pieces undergo a process technically termed ageing. This was formerly effected by spreading out the pieces, and hanging them in a room for three or four days, so that the acetate of alumina might lose part of its acetic acid, and the iron mordant nearly the whole of it, thus liberating the oxide of iron and enabling it to undergo partial oxidation.

Some few years ago, Mr. David Thom introduced a process by which this is effected in twenty minutes; it consists in passing the printed mordanted cloth over rollers fixed in a machine placed in a chamber about twenty feet long, in which a current of air and steam is thrown. The temperature of this chamber must not be below 100° nor above 108°, and the quantity of steam present must be such that 50 yards of calico will take up one ounce of moisture during the twenty minutes it takes to pass through the chamber. The printer is able to test the state of the chamber by means of wet and dry bulb thermometers. The next operation to which the cloth is submitted is dunging. The process received this name because formerly the calico was passed through a mixture of cow-dung with water. Now, however, silicates or arseniates of soda, mixed with a little chlorate of potash, are substituted. After passing through either of these solutions they are washed, and ready to be passed through the dye-beck. This beck contains water, and from five to seven pounds of madder, or one to two and a half pounds of garancine, or commercial alizarine, for each piece of calico to be dyed. The heat of the bath is then gradually raised, by means of a jet of steam, to 180° for garancines, or 212° for madders. This operation takes from one and a-half to two hours, according to class of goods, style, &c. The fabrics are then washed and passed through a cleansing liquor for garancine or commercial alizarine styles, or soaped twice at 180, when they are dyed with madder.

The most permanent and brilliant colour produced from the *Rubia* plant on cotton fabrics is Turkey red. The details so essential to success in dyeing this colour are kept by each dyer a secret, but I will attempt, as briefly as possible, to give the main features of the process. After the bleaching of the fabric is completed, they are passed through Gallipoli oil, and then exposed to the atmosphere in heated chambers. This operation is repeated several times. The next one consists in passing the cloth through a weak alkaline solution. After this they go through a solution of acetate of alumina, and then through a bath of a tannin substance. By these processes, no doubt, the fatty acids of the oil combine with the alumina, as does the tannic acid of the tannin matter, helping to fix the mordant in the fibre of the fabric. On being dyed, the goods assume a rich, dark red tone, to which brilliancy is imparted by passing the dye fabric through heated soap solutions.

I should occupy too much of your time were I to attempt to enter into the details of the methods by which chemists determine the relative tinctorial powers of roots, madders, and garancines, but I may give you a very

simple method of detecting ordinary adulterations of garancine by dye woods and tanning matters. Pieces of blotting paper are dipped into a weak solution of chloride of tin and sulphate of protoxide of iron, and on each of these sheets is sprinkled a little of the suspected garancine. If a dye wood be present, the chloride of tin paper will assume a red colour, and if tannin matter be present, the iron paper will be blackened.

(To be continued).

NOTICES OF BOOKS.

Notices on Nuisances, Drains, and Dwellings. By W. H. PENNING, F.G.S. London: Baillière and Co.

MR. PENNING tells us that his pamphlet was written during a period of incapacity for his usual avocations, and most sincerely do we wish that such periods could be so usefully employed. The author deals with sewer-gas, the escape of ordinary gas, decaying organic matter, damp, and smoke as nuisances, giving subsequent chapters on ventilation, air-shafts, and the general prevention of nuisances. The remarks show much common sense, and are easily applicable.

Notes of Fifteen Lectures on "Physics and Chemistry."

Delivered by Professor GUTHRIE, in the Lecture Theatre of the South Kensington Museum during January and February, 1872.

THESE are the notes of lectures delivered in the course of instruction in Science and Art for Women by Professor Guthrie. Quietly pursuing course after course of lectures, Dr. Guthrie has done and does more for the advancement of science than many whose names are daily before the public. In these notes we have the sum of this department of Professor Guthrie's work. To the lecturer, the teacher, and the student of chemistry and physics the notes will be most valuable; to the lecturer and teacher they will afford a basis of discourse; to the student they will prove an admirable means of self-examination. In the recapitulation or "Gossip" on his lectures, Professor Guthrie speaks with the greatest point. Says he—"The heavenly bodies in their orbits are types of the particles of matter which we handle. Call these small parts particles if you please, or call them molecules, but do not call them atoms: do not write '*finis*' to the book of nature." Most sincerely is Professor Guthrie to be congratulated on the successful issue of his work at South Kensington.

Index to Gmelin's Handbook of Chemistry. By HENRY WATTS, B.A., F.R.S., F.C.S., Editor of the "Journal of the Chemical Society." London: Harrison. 1872.

EVERY chemist will rejoice to learn that the Index to "Gmelin" is published. We need not dwell upon the advantages of the possession of a complete series of this admirable and exact work, for the volumes are generally regarded as indispensable to the shelves of the chemist. So great is the demand that several of the volumes are out of print, and others are very scarce. It being probable that now the Index is published there will be a call upon the later volumes of the work, we recommend our readers to order their copies at once to prevent disappointment. The concluding volume (the 18th) and the Index, are included in the subscription to the Cavendish Society for the year 1864. It need not be said that the arrangement of the Index is thoroughly logical, every compound being taken under as many heads as possible to facilitate reference. The employment of Arabic numerals, but in different types, in referring to both volume and page, is much to be commended as preventing confusion. In a word, the announcement that the work is complete, will be deemed in our pages a sufficient notice.

CORRESPONDENCE.

PROPOSED ASSOCIATION OF MANUFACTURING CHEMISTS.

To the Editor of the Chemical News.

SIR,—As manager of one of the largest chemical works in Lancashire, may I express the great gratification with which I have read the two able letters of your correspondents, and your own clear and cogent exhibit of reasons in favour of an association of manufacturing chemists. To illustrate how one manufacturer may communicate valuable information to another without being any the poorer for it, perhaps you will allow me space for the following brief statement of fact:—There is an extensive chemical manufacturer in this district, who has just re-leased, and divided into smaller ones, two immense vitriol chambers: the legacy to him of a time when everybody built them of enormous size. As each of these large chambers represented one-third of his entire chamber capacity, the simple result was that, by the dislocation, his manufacturing power was reduced one-third, while, at a ruinous cost, he had to buy vitriol to make up the deficiency during the whole time of the repairs. Of course the stoppage and repair of a chamber one-fourth the size of these would only have reduced his producing calibre one-twelfth—a mere bagatelle. One would think that considerations like this would be patent to the merest tyro in scientific manufacturing; but they are not, for—influenced solely by the relatively paltry object of saving lead—owners of works are still to be found putting up chambers of very large size. I conclude by remarking that if any intending vitriol maker is guided in his erections by what I have said, he may save many hundreds of pounds by what has cost me only

PEN AND INK.

To the Editor of the Chemical News.

SIR,—It may seem strange for an engineer to express an opinion upon the proposal for an association of manufacturing chemists, but I have long had an opinion that such an association would benefit all concerned. I only hope that should such a society be formed, membership will not be limited to the profession strictly.

One can hardly exaggerate in statements as to the difficulty of obtaining reliable information on chemical matters, more especially as to the quantity of work performed in plants of certain size and the cost of the said work. In answer to enquiries and questions, I have had replies so widely different from divers persons that I am obliged to suppose some of them have been concocted for the express purpose of misleading.

Of course no society can exist successfully unless the members from the outset studiously avoid all attempts at concealment or misleading; and, on the contrary, endeavour to exchange ideas as much as possible.—I am, &c.,

THOS. WILKINS.

Adelaide Chambers, 52, Gracechurch Street,
July 6, 1872.

PS.—Re Coffey's stills for ammonia. About four or five years ago Messrs. Packard, of Ipswich, erected one at their Bramford works; it was working one or two years to my knowledge, and may still be so.

The description in Muspratt is hardly correct in detail, and is likely to mislead. I shall be pleased to give your correspondent what information I can, having had to do with these stills for the distillation of spirits, &c.—T. W.

To the Editor of the Chemical News.

SIR,—I am very glad to be able to endorse the feeling in "Frank's" letter of last week but one. Such a society

as he proposes should surely soon be got together and in working order; and I would propose Manchester as a centre for the local society of Lancashire manufacturers. That it would be of great benefit to its members can scarcely be doubted. The old days when manufacturing chemists were, the bulk of them, simply a set of quacks and dabblers in drugs are over, or at any rate nearly so, and with them have gone most of the petty jealousies and paltry pickings and stealings of secrets, mean spying, and all the other offspring of the then state of ignorance (it is no longer a reproach to be called a theoretical chemist). I myself have perceived what must have made itself apparent to many others, that a much better and healthier tone has arisen within this last twenty years. A conversation with a fellow manufacturer or manager is no longer a fencing match—an attempt to acquire the largest amount of information, at the same time imparting as little as possible. There is much knowledge of such a general kind that can be imparted without at all impoverishing the giver. It makes no one the poorer to say the size and strength of the timbers for a vitriol chamber, or how much sulphur or pyrites he burns for a given chamber space: all this forms simply common gossip. The Literary and Philosophical Society of Manchester only partly serves "Frank's" object; its tone is more high science, with only comparatively a sprinkling of technology, whereas the proposed society, I take it, would confine itself to questions of a technical bearing only. In conclusion, I can only add that I shall be glad to render all the assistance I can in carrying out the movement.—I am, &c.,

PETER HART.

Ardwick Bridge Chemical Works,
Manchester.

THE CAVENDISH SOCIETY.

To the Editor of the Chemical News.

SIR,—As one who has benefitted by the publications of the Cavendish Society, and desires a continuance, I wish to know if there is any reason why it is not, as in years gone by, busily engaged in the translation and publication of English and foreign works treating of the various branches of the science studied with such lasting effect by him whose name it bears? Is it that its object is now less important than it was at its foundation? Are there not now-a-days works published—or which would be published if any sufficient inducement were offered—here, on the Continent, and in America, of equal sterling worth to those published hitherto by the Cavendish Society, which remain either entirely, or to a great extent, unknown to us in Britain for want of some such Society to carry on this work? Or is it, that though the object is as important as ever, and the material as abundant, the society must be dissolved for lack of funds?

The above, it appears to me, are the main reasons why such a society should be allowed to decline, and none of them I am persuaded, nor all combined, are of such weight at the present time as to render it necessary to give up the Society altogether. Perhaps some of those concerned in the management may be able to furnish reasons why it has sunk to such a low ebb; but is it not a matter to be urged upon the consideration of the Council—if such still exists—to revive, and re-model as far as necessary, the existing society, and to continue the good work which it has so well done in the past?

Are there not some of the works of its founders and officers,—Faraday, Graham, Hofmann, Daubeny, Miller, Stenhouse,—as well as others, which are so scarce that their publication by the Society would be a boon to many, and which would remunerate the Society for its trouble in publishing them?

Mr. C. Tomlinson, in his letter of January 24, 1870 (CHEMICAL NEWS, vol. xxi., p. 44), spoke of the dissolution of the Society on Messrs. Harrison having com-

pleted the publication of the works in hand. Perhaps he, or Mr. Watts, will favour us through your columns with the views of the Council on these points, and it is to be hoped that by bringing the matter before your readers their attention may be arrested, and the result may be such expressions of opinion and interest as will lead to the reusucitation of this useful Society. That such may be the case is the wish of—Yours truly,

W. H. WOOD.

Halifax, July 5, 1872.

MISCELLANEOUS.

Royal School of Mines.—At a meeting of the Council held on July 6, the Associateship was conferred on the following gentlemen:—Mining and Metallurgical Divisions—O. Pegler, W. Charlton. Mining and Geological Divisions—G. M. Dawson. Mining Division—E. Dillon. Metallurgical Division—F. W. Harrold, J. H. Huxley, O. F. Monday, A. G. Phillips. The following awards were made:—First year students—The two Royal Scholarships, £15 each, to Mr. S. A. Hill and to Mr. J. Taylor. Second year students—H.R.H. The Duke of Cornwall's Scholarship to Mr. Edgar Jackson, the Royal Scholarship of £25 to Mr. C. Law, and the Murchison's Medal and Prize of Books in Geology to Mr. S. W. Davies. Third year students—The Edward Forbes's Medal and Prize of Books in Natural History and Palæontology to Mr. G. M. Dawson. The De la Beche Medal and Prize of Books in Mining to Mr. W. Charlton.

New Quicksilver Assay.—The following description of a new method of assaying quicksilver ores, by A. Eschka, is taken from the *Berg-und hüttenmannische Zeitung*. The new assay may be used for cinnabar, mercuriferous Fahlerz, &c. The ore should be weighed in a balance turning with one milligramme. The quantity of ore for the assay varies according to its richness, as follows:—

Ore containing up to 1 per cent	10
" " 1 " 10 "	5
" " 10 " 30 "	2
" " over 30 "	1

The ore is introduced into a porcelain crucible, the edge of which has been ground flat, and mixed with about half its weight of clean iron filings, by means of a glass rod, and is then evenly covered with a layer of iron filings about $\frac{1}{4}$ to $\frac{1}{2}$ inch thick. A concave cover, made of fine gold, about 2 inches in diameter and 12 to 15 grammes in weight, is now placed on the crucible after having been carefully weighed; the concavity is filled with distilled water and the crucible placed on a triangle and heated for ten minutes by a Bunsen burner or Argand spirit-lamp, during which time the mercury is volatilised and deposits itself on the gold. The gold cover is then removed, the water poured off, and the mirror of mercury on the convex side washed with alcohol from a wash bottle. After being dried in the water-bath the cover is allowed to cool thoroughly, and is then weighed in a balance turning with $\frac{1}{4}$ milligramme with 50 grammes in the pan. The increase of weight gives the quantity of quicksilver in the ore. During the weighing the cover is placed on an empty porcelain crucible. The quicksilver is then driven off by heating the cover gently in the flame of a Bunsen burner or a spirit-lamp, in a place where there is a good draught, and the empty crucible and cover are subjected to a second weighing as a check. In order that the assay should succeed the following conditions must be fulfilled:—The cover must fit closely, so as to avoid loss of quicksilver, and must be deep enough to hold a sufficient quantity of water to keep it cool. The iron filings must be free from grease, which would prevent the proper formation of the mirror; the washing with alcohol must

not be omitted, as it removes all the bituminous substances, which spoil the mirror and assist the drying; drying in a water-bath for two or three minutes; cooling in the exsiccator; weighing when fully cool. When assaying rich ores the alcohol used in washing the cover must be collected, as it may contain a little amalgam; it must be poured into the concavity of the cover, which will take up any little globules of quicksilver. The most exact results are obtained in the case of poor ores containing less than 10 per cent.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 10, 1872.

In addition to several important papers relating to mechanical, mathematical, and natural history sciences, this number contains the following papers more particularly bearing upon chemistry:—

New Method of Printing upon Woven Tissues by means of Metallic Precipitates.—E. Vial.—The author describes, at considerable length, a peculiar process of printing upon woven tissues, by first impregnating the same with a solution of nitrate of silver, or of any other metallic salt which, on being brought into contact with either metallic zinc or copper, is so decomposed as to set the metal free, and next printing on the tissue so treated a pattern by means of zinc or copper plates; the result being that, wherever contact between the metal and tissue (treated as just mentioned) takes place, there is formed a precipitate of the metal (silver, in case the woven fabric were impregnated with nitrate of silver), which is at once indelibly fixed to the cloth, presenting, according to the strength of the silver solution employed, a colour varying from a bright grey to an intense black. The colour is exceedingly fast, resisting the action of alkalis, acids, and soap.

Researches on the Trichloracetates.—A. Clermont.—After briefly referring to his former researches on this subject (see *CHEMICAL NEWS*, vol. xxv., p. 202), the author describes—Acid trichloracetate of ammonia, $\text{NH}_4\text{O}_2\text{C}_2\text{Cl}_3$. This salt is not decomposed at the ordinary temperature of the air, but on being heated it gives off trichloroacetic acid, while chloride of ammonium is formed. 100 parts of the salt contain—Ammonia, 7.55; trichloroacetic acid, 89.82; water, 2.63. Acid trichloracetate of thallium, $\text{TlO}_2\text{C}_2\text{Cl}_3$, a beautifully-crystalline salt obtained by dissolving carbonate of thallium, in an excess of trichloroacetic acid. 100 parts of this salt consist of—Oxide of thallium, 40.0; trichloroacetic acid, 58.30; water, 1.70. Neutral trichloracetate of thallium, $\text{TlOOC}_2\text{Cl}_3$, also a crystalline body, contains, in 100 parts—Oxide of thallium, 57.84; trichloroacetic acid, 42.16. As regards the action of permanganate of potassa upon hydrate of chloral, it appears that the salt just alluded to oxidises hydrate of chloral very energetically, the result being the formation of trichloroacetic acid, which remains in the liquid combined with potassa.

June 17, 1872.

This number contains the two following papers relating to chemistry:—

Combination of Stannic Acid with Anhydrous Acetic Acid.—M. Laurence.—By heating to 150° , in a sealed tube, a mixture of 2 parts of anhydrous acetic acid and 1 part of meta-stannic acid, previously dried at 100° , there is obtained a syrupy liquor, which deposits, on cooling, long needle-shaped crystals. On being first roughly dried between folds of filtering-paper, and then in vacuum, they lead, on analysis, to the following cyphers, in 100 parts:—Tin, 33.33; acetyl, 48.58. Formula—

When the same crystals are washed with anhydrous ether until that fluid takes up no more acid, and the substance is again dried in vacuum, the per cental composition is the following:—Tin, 46.22; acetyl, 54.1. Formula—

When the crystals are exposed to air, they become amorphous and

exhibit a vitreous mass, which, on being analysed, led to the following results:—In 100 parts—Tin, 56.19; acetyl, 21.0. Formula—

New Phospho-Platinic Compound derived from Toluidine.—G. Saillard.—After first referring to Dr. Schützenberger's researches on phospho-platinic compounds, the author states that, by heating an alcoholic solution of the ether, $\text{Ph}(\text{C}_6\text{H}_4\text{O})_2\text{PtCl}_2$, with an excess of crystallised toluidine, there is obtained a product which, after having been purified and dried at 100°, yields, on analysis, the following per cental results:—Ph, 5.73; C, 28.83; H, 4.43; N, 2.59; Pt, 36.43; Cl, 13.12. The reaction which takes place is exhibited by the following formula:—

This number contains some very important papers and memoirs bearing upon meteorology, astronomy, natural history, and geology.

La Revue Scientifique de la France et de l'Etranger,
June 22, 1872.

This number, delayed in transmission, contains no original papers relating to chemistry, but we may call attention to the following important memoir:—

Civilisation Considered as Accumulated Force.—L. Dumont.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 11,
1872.

This number opens with an admonition on the part of the treasurer of the Society, whereby the members are reminded that, in accordance with section 23 of the statutes, any member who, after having been twice requested in writing to pay his contribution, fails to do so, ceases to be a member *hoc ipso facto*, and his name is peremptorily struck from the roll.

The following original papers and memoirs are contained in this number:—

Isobutyric Acid from Citra-bibrom-pyrotartaric Acid.—F. Geromont.—The main gist of this short paper is that, according to the researches of Kekulé, the acid obtained by the action of sodium amalgam and water upon citra-bibrom-pyrotartaric acid must be constituted according to either of the two following formulæ:—

On Hypophosphites.—C. Rammelsberg.—In the introduction to this lengthy memoir, the author reviews the labours of Dulong, H. Rose, H. Davy, Würtz, and others on this subject. The mode of decomposition of the salts alluded to, when exposed to the action of heat, is then discussed at great length. It appears that in some cases the result of the decomposition of hypophosphites by heat is the formation of a mixture of pyro- and meta-phosphate. The hypophosphites of nickel and cobalt leave, on ignition, a mixture of meta-phosphate and phosphuret of the metal. Hypophosphites of ammonium yields, on ignition, 1 molecule of pyrophosphoric, and 2 molecules of meta-phosphoric acids. The hypophosphite of uranium is converted into phosphate of protoxide of uranium, a conversion attended with explosion, in consequence of the sudden evolution of hydrogen gas.

Most Simple Method of Determination of the Molecular Weight as Deduced from the Volume of Vapour.—H. Landolt.—This paper is illustrated with a woodcut, the reproduction of which would be essentially required for the proper understanding of the contents.

Oxidation-Products of the Benzyl-Ketons.—A. Popoff.—In the introduction to this essay, the author discusses the general principles of the oxidation of the benzyl-ketons, and next treats on benzyl-methyl-keton, which, having been obtained in a state of perfect purity, and exhibiting all the properties described by Radziszewsky, was oxidised by means of bichromate of potassa and sulphuric acid, yielding benzoic and acetic acids. This oxidation took place according to the following formula:—

Benzyl-ethyl-keton, having been prepared, was also oxidised, the result being the formation of benzoic and propionic acids. This reaction is elucidated by the following formula:—

Concentration of Sulphuric Acid.—R. Hasenclever.—Reserved for full translation.

Heat of Formation of the Nitrogen Acids.—J. Thomsen.—This paper is a criticism of the labours of Berthelot on this subject.

Contribution to our Knowledge on Cholesterin.—W. Loeblisch.—This essay treats on—The products of oxidation of cholesterol, viz., a new acid, $\text{C}_{26}\text{H}_{48}\text{O}_8$, a solid, crystalline body, readily soluble in alcohol, ether, and warm acetic acid; acetyl-cholesteryl, also a solid crystalline compound, formula—

cholesterylamin, $\text{C}_{26}\text{H}_{48}\text{NH}_2$. The author quotes the cholesterol compounds in the following manner:—Cholesterin, $\text{C}_{26}\text{H}_{48}\text{OH}$ sodium-cholesteryl, $\text{C}_{26}\text{H}_{48}\text{ONa}$; acetyl-cholesteryl—

chlorcholesteryl, $\text{C}_{26}\text{H}_{48}\text{Cl}$; cholesterylamin, $\text{C}_{26}\text{H}_{48}\text{NH}_2$.

Nitro Compounds of the Fatty Series.—V. Meyer and O. Stüber.—This, the second instalment of a lengthy monograph on this subject, is divided into the following sections:—Metallic derivatives of nitro-ethan; nitro-methan.

Absorption of Ozone in Water.—L. Carius.—The author has instituted a series of experiments from which it appears that ozone is measurably absorbed by water, and that in the commercially-sold ozone-water (at Berlin, Krebs, Kroll, and Co., manufacturers) there is really contained ozone (not nitrous acid or peroxide of hydrogen) to an amount of about 4.45 c.c. in 1000 c.c. of water at 0° and 0.76 m. barom.

Some of the Pigments and Dyes derived from the Aromatic Azo-Diamines.—Dr. A. W. Hofmann and A. Geyger.—This second portion of a monograph on this subject treats on—Safranine; nitrate of safranine; platinum salt of safranine; the free base; chloride of safranine; picrate of safranine; iodhydrate of safranine; sulphate of safranine. The eminent authors call attention to the curious coincidence of the formulæ of safranine, $\text{C}_{21}\text{H}_{20}\text{N}_4$, and Perkin's mauvein, $\text{C}_{21}\text{H}_{20}\text{N}_4$, stating that the latter might almost be considered as phenylated safranine, $\text{C}_{27}\text{H}_{22}\text{N}_4 = \text{C}_{21}\text{H}_{16}(\text{C}_6\text{H}_6)\text{N}_4$. When safranine is boiled with aniline, a violet dye is obtained; and when treated with concentrated acids, safranine and mauvein yield the same reactions.

Les Mondes, July 4, 1872.

Native Vegetable Ink.—Rev. F. Moigno.—The author states that experiments are being made to acclimatise in Europe the *Coriaria thymifolia*, or ink-plant of New Grenada. The juice of this plant, locally termed *chanchi*, is at first of a somewhat reddish colour, but becomes intensely black in a few hours. This juice can be used for writing without requiring any further preparations; it corrodes steel pens less than ordinary ink, and has, moreover, the advantage of better resisting chemical agents. When the portion of America named above was under Spanish dominion, all public documents were written with *chanchi*, which was not removed from paper by sea-water.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
April 25, 1872.

Gas-Making Apparatus for Domestic Use.—M. Symer.—The detailed description of an apparatus suited for the manufacture of illuminating gas, more especially for use in dwelling-houses, country seats, railway stations, &c., situated at a great distance from public gas-works.

Newly-Devised System of Purifying the Condensation Water of Low Pressure Steam Engines.—M. M. Cail and Co.—The authors first refer to the various methods now in use for purifying—that is to say, freeing from grease and oily matters—the condensed steam of the low pressure engines, so as to render the resulting water fit for use again as feed-water of the boilers. They next describe their invention, which mainly consists of a contrivance by which the water is agitated with benzoline (light petroleum oil), which dissolves the fatty matters, leaving the water in a pure state. The benzoline may be rendered, after having become saturated with fatty matters, fit for renewed use by distillation, while the fatty substances may be used for soap-making and other purposes. From the authors' experiments it appears that from 1.5th to 1 grm. of fatty matters per horse-power is daily taken up by the condensation water; benzoline of good quality can take up more than half its weight of fatty matters before becoming inactive; other liquid hydrocarbons may also be taken.

Note on the Native Calcareous Phosphates (Phosphorite) of the Département du Lot.—C. Mène.—This paper, illustrated by woodcuts exhibiting sectional views of the quarries, gives a detailed account of the exploitation of this mineral, now carried on to a large scale.

Testing of Wine, Beer, and Vinegar.—Dr. Duclaux.—The author, briefly describing a system of testing the relative value of the liquids referred to, states that, when alcoholic or acetic liquids are caused to pass drop by drop from a narrow orifice, these drops are heavier in relation to the larger quantity of alcohol or acetic acid contained in the liquid under examination. Special apparatus are to be used for this method of testing.

Bibliography.—Under this heading we notice the following work:—"La Pomme de Terre sa Culture, son Emploi et sa Conservation," by M. E. Vianne, Paris.—A. Sagnier.—This work,

illustrated by woodcuts, is very highly spoken of. The author, an eminent agriculturist, treats the subject agriculturally as well as industrially.

May, 2, 1872.

Bone-Black Manufacture.—C. Mène.—The detailed account of the modes and process of bone-black preparation as carried on by MM. Dunod and Bougleux. This industry includes, besides bone-black for sugar-refining purposes, the manufacturer of empyreumatic oil, bone-grease, sulphate of ammonia, superphosphate of lime, bone-dust, bone-ash, and bone-black for paint and blacking purposes.

Description of Apparatus for the Preparation of Gases in Chemical Laboratories.—J. Salleron.—Illustrated by woodcuts. The author gives an account of well and strong made cast-iron apparatus suited for making oxygen, coal-gas, and other gases, which require a strong heat for their preparation.

Continuation of the Essay on Dynamometers.—C. Mène.
Liquefied (Condensed) Sulphurous Acid Gas for the Preservation of Beet-roots.—Ch. Tellier.—Sulphurous acid gas is condensed and forced into portable vessels made of cast-iron, and the liquid dispersed through the beet-roots, which are kept in pits dug in the field and covered by earth; the gas is liquefied on the large scale by the combined agency of pressure and cold.

Bromine Water as a Test for Phenol.—C. Mène.—When bromine water is added in excess to a weak aqueous solution of phenol, there is formed a yellowish white precipitate of tribromophenol; this reaction is so sensitive that 1 part of phenol (carbolic acid) in 4370 parts of water, that is 0.0229 grms. to the litre, can be detected; in case of any doubt arising as to the nature of the precipitate, it is separated by filtration, washed, and put into a test-tube, gently heated along with some sodium amalgam; the liquid is then poured into a beaker-glass, and upon the addition of a few drops of dilute sulphuric acid the characteristic smell of phenol will be perceived, and the substance becomes visible in the shape of oily drops.

Bibliography.—Under this heading we meet here with a review from the pen of Dr. Pisani of the work—"Détermination Pratique des Minéraux," by M. E. F. de Kobell. Paris: J. Rothschild, 13, Rue des Saint-Pères. It appears that this small work is a highly valuable book both for chemists and mineralogists to aid them in rapidly and accurately ascertaining the nature of minerals.

NOTES AND QUERIES.

Parnell's Process for Estimation of Arsenic in Ores.—I should feel obliged if your readers could inform me where I may obtain full particulars of Parnell's process for estimation of arsenic in ores by means of chlorine, as briefly described in Crookes's "Select Methods of Chemical Analysis."—G. W.

TO CORRESPONDENTS.

C. A. Priestley.—Apply chlorine-water with a camel's-hair brush, and wash with distilled water.

W. Morgan Brown.—We are obliged for the copy of Lightfoot's "Chemical History and Progress of Aniline Black."

G. E. Davis, W. H. Wood, and W. E. Bickerdike.—Received with thanks.

W. W.—There is a good article on Indigo in the English edition of Wagner's "Chemical Technology," just published by Messrs. J. and A. Churchill.

W. P.—Consult Watts's "Dictionary of Chemistry."

B. Westermann and Co. (New York).—We have just received a letter from these correspondents, from which we quote the following:—"In CHEMICAL NEWS, vol. xxv., p. 71, under the heading "Bibliography," you state the price of Knapp's "Technische Wandtafel," 64 coloured plates, &c., as £6 10s., which is evidently a mistake, the price for each of those 64 plates being R. 2. 10 groschen, or 7s. English, if four are taken at once; single plates selling at R. 2. 25, or 8s. 6d. The entire collection of 64 plates would cost, therefore, at 7s. each, £22 8s., and not £6 10s." We hasten to rectify the error, which, however, was not ours, as we correctly translated the price from the German periodical.

VOL. XXV. No. 660.

ON THE DETECTION OF ORGANIC AND OTHER NITROGENISED MATTER EXISTING IN THE ATMOSPHERE.*

By ALFRED HUTCHISON SMEE, F.C.S.

IN this communication the author describes a method which he has devised, and which he names "distillation by cold," by which he believes the detection and determination of ammonia and other organic impurities existing in the atmosphere will be greatly facilitated.

A glass funnel (usually of 8 or 9 inches) is drawn to a point and closed. It is supported in an ordinary stand, and filled with ice. Condensation of the watery vapour of the atmosphere then takes place; the dew collects into drops, which trickle down the outside of the funnel, and at last fall from the point, under which a small receiver is placed to catch them. The total quantity of liquid collected in a given time is measured, and the quantity of ammonia determined by Nessler's test.

By the method of distillation by cold, the author found it possible to distil many substances which are decomposed at a high temperature. Thus many delicate odours of flowers were distilled by placing the flowers under a bell-glass sufficiently large to cover the funnel containing the ice. The odours were found to be more rapidly and completely abstracted by placing a dish with a little ether under the bell-glass at the time of distillation.

The Paper was accompanied by tables giving the results obtained in 107 experiments, together with the atmospheric conditions prevailing at the time. The experiments were made in a garden, in a bed-room, in hospital wards, in the open country, &c. A few of the numbers obtained are here given by way of example:—

Fluid collected in minims.	Ammonia in grains per gallon.	Source.
150	1'9712	Erysipelas.
120	0'1791	Garden.
55	6'8807	Drains.
90	2'1000	Bed-room.
	2'9568	Stables.
150	0'0985	Victoria Park.

IMPROVEMENTS IN CHLORIMETRY.

By GEORGE E. DAVIS.

THERE is a modification of Penot's arsenic method for the estimation of the available chlorine in bleaching-powder now extensively used in commercial laboratories. It has not, however, found its way into many text-books on analysis; the process is as follows:—

Standard Solution of Arsenious Acid.—Weigh off 13'95 grms. of arsenic trioxide, dissolve in caustic soda solution, dilute largely with water, acidify with hydrogen chloride, and dilute exactly to a litre. 10 c.c. of this solution correspond to 0'1 grm. chlorine.

Indicator.—A concentrated solution of indigo sulphate.

Preparation of the Solution of Bleaching-Powder.—After well mixing the sample, weigh off 5 grms. of the powder and rub up with water to a paste, add more water and allow to settle, pour off the nearly clear liquid into a 250 c.c. flask, and repeat the operation until the whole of the powder has been transferred to the flask in the state of

solution and fine division, then fill up to the mark with water.

The Analysis.—Take 10 c.c. of the standard solution of arsenious acid, place in a small flask, and add a drop of the indigo sulphate solution. Fill a burette (Gay-Lussac's I prefer) with the bleaching-powder solution which has been well agitated, and add it cautiously to the arsenious acid until the blue colour of the solution is replaced by a brownish yellow. The number of c.c. used must then be divided into 500, which will give the percentage of available chlorine in the powder under examination.

Some operators object to use the process because they say it gives low results, for an excess of bleaching-powder solution is required to oxidise the indigo sulphate, and the more bleaching-powder used the lower the results. This is true partly, but only *one drop* is required to oxidise the indigo, just as one drop in excess of hyposulphite is required to decolourise the iodide of starch in Bunsen's method.

Then, again, others say that it is not advisable to run the bleaching-powder solution into an acid solution, as some chlorine might be liberated and lost. Such objections as these are only puerile, and do not in the least tend to weaken the liking many operators have for the process, those who have tried it and have found it to work most satisfactorily. Now to work upon the theory of the process, all that is wanted is to dissolve the arsenic trioxide in a substance which shall be inactive, as far, at least, as regards the arsenic trioxide, the indigo sulphate, and the bleaching-powder solution. Water will not dissolve the oxide without a great deal of trouble; alkalies dissolve it easily with the production of arsenites, but these alkalies have to be taken up again by adding stronger acids, being only used for easily obtaining the arsenic in a soluble form; but glycerine dissolves arsenic trioxide easily; glycerine is not acted upon by the bleaching-powder solution or by the indigo sulphate, therefore it is specially adapted for the preparation of the standard solution. I now prepare my standard solution thus:—13'95 grms. of arsenic trioxide (which has been powdered in an agate mortar) is heated in a flask with 40 c.c. of pure glycerine until it is all dissolved; the solution is then diluted with distilled water to a litre, when it is ready for use. It is of course of the same strength as that prepared by dissolving in caustic soda and afterwards acidifying with hydrochloric acid, and is used in exactly the same way.

A litre of solution was made by each method and was used side by side for a long series of trials, in order to determine whether the method was reliable or not, with the following results:—

	Bunsen's Method.	Arsenic dissolved in Alkali and Acid.	Arsenic dissolved in Glycerine.
1.	36'72	36'64	36'64
2.	29'82	29'71	29'78
3.	25'86	25'80	25'80
4.	26'58	26'58	26'66
5.	31'33	31'42	31'38
6.	34'41	34'36	34'36
7.	7'16	7'04	7'06
8.	7'18	7'11	7'13
9.	8'33	8'42	8'39

The last three were samples of bleaching liquor, the first two of which were warranted to contain between 7 and 8 per cent of available chlorine and the third 9 per cent.

I find there is a method for testing bleaching-liquor, used in several manufactories which gives an error directly as the specific gravity of the liquor. The analysis should be conducted as described above, but the bleaching-liquor solution should be made as follows:—25 c.c. of the liquor should be diluted to 250 c.c., and then added to the arsenious acid solution, the number of c.c. used multiplied by the specific gravity, and divided into 100 will give the percentage of available chlorine in the liquor. Now some forget to divide by the specific gravity, consequently the percentage is expressed higher than it really is, to the

* Abstract of a Paper read before the Royal Society.

extent of about 1 per cent, for 25 c.c. are in the calculation reckoned as 25 grms., whilst in reality the weight is 28.5 grms. if the liquor possesses a density of 28° Twaddle, which is 1.14 specific gravity.

The turbid solution of bleaching-powder must always be used, and never filtered, or be allowed to settle; for the clear liquid always gives lower results, showing that the insoluble portion carries down chlorine with it, as the following analyses will show:—

	Bunsen's.		Modified Penot's.	
	1.	2.	1.	2.
Turbid ..	38.14	38.09	38.00	38.21
Clear ..	37.41	37.60	37.36	37.72

These determinations were made upon two different weighings of the same powder. No. 1 was brought into solution and estimated first by Bunsen's method, and then by the modified Penot's; the liquor was then allowed to settle, and the clear fluid examined. No. 2 weighing was served in the same manner.

The absence of this method in two at least of our best text-books, and the easy way of preparing the arsenious solution in glycerine, with the advantage of the indicator being in the solution itself, led me to describe it. It is not for the scientific analyst I have done so, but for many manufacturers and consumers of the article who, perhaps, are only acquainted with imperfect or indirect methods; but the solution in glycerine is a novelty; at least I have never seen it described before.

Radcliffe, July 2, 1872.

ON PYRO-PLATING.

By J. BAYNES THOMPSON.

THE end of pyro-plating, like that of all other methods of plating, is to affix to a baser metal a sheet of one of the superior metals; but this method is applicable where none of the other methods can be applied with success.

"Close plating," whether with hard or soft solder, cannot be applied with success to any cutting instrument, as a knife or a pair of scissors, &c. Hard soldering would completely destroy a knife-blade or a pair of scissors. The soft solder plating can be applied to a knife or a pair of scissors without destroying the steel, though with difficulty; with the scissors the first attempt to cut would shear off the plating, and with the knife, if it were sharpened so that it would cut, the plating would chip off in using it. Common electro-plating is not applicable to steel or iron, as by that method these metals cannot be got perfectly clean, that is—chemically clean, therefore by that method no adhering coating can be obtained.

In fact, for all manner of plating or soldering, the first requisite is, that the two metals that are to be applied to each other must be chemically clean, or no proper adhesion can be obtained.

This cleanness is obtained in various ways. In soldering by various fluxes; in electro-plating to such metals as that method is applicable; by dipping the article in an acid which will readily dissolve the metal of which it is made,—and not only so, but the salt formed by this solution of the metal in the acid used, must be readily soluble in water, or no clean surface can be obtained. There is still another condition to be considered, that is when the surface of the metal has been made thoroughly clean, it must be protected from contact with the air in its transit from the cleansing-baths to the solution wherein it is to be coated. This condition not being recognised in the first attempts at electro-plating caused many failures and much trouble, till it was discovered that a film of mercury prevented the contact of the air with the cleaned metal. Moreover, mercury has this advantage, that it amalgamates with the metal to be coated, and with the coating, though this amalgamation is not absolutely necessary, yet it

facilitates the coating of metals with other metals by electro-deposition, when the two metals will readily amalgamate.

There are cases where amalgamation is not possible; for example, where one of the metals will not amalgamate, as with steel and iron coated with copper, gold, or silver; or when neither will amalgamate, as with steel or iron coated with aluminium or nickel; not that it is impossible to form an amalgam with these metals, for even steel can be amalgamated by the intervention of sodium, but it is not possible for plating purposes, as a diluted solution of a mercuric salt must be used.

Now for all such cases as these where the amalgamation process cannot be used, pyro-plating is especially applicable. The name pyro-plating is given to this process to distinguish it from the Electro-plating process, and because the coating is driven into the surface of the metal on which it is put by means of heat and pneumatic pressure. It is not confined to coating with silver as its name might indicate, but it is at present applied to coating with gold, platinum, silver, nickel, aluminium, copper, brass, or bronze and aluminium bronze.

The rationale of the process is very simple; but the various details require much care and attention.

The end to be obtained is simply this. That the metal to be coated shall be "chemically clean" when immersed in the solution in which it is to be coated. There are several ways in which the attainment of this end may be prevented. By inadequate means for cleansing, by the passage through the air of two or three feet after being cleansed, by the metal being positive in the coating solution,—in this case the metal is fouled on contact. This refers to cyanide solutions, to sulphate and chloride solutions, to double sulphates and chlorides, as of nickel and ammonia, and of platinum and potash or soda. All of these may be used in certain cases for pyro-plating, but they are *not* used. There is a special solution used for pyro-plating in all cases, because most of these solutions leave matters in the metal that is being coated, if it be in the slightest degree porous or "roaky," as is the case with steel that has been badly faggoted, and on the article passing through the furnace these matters volatilise, and cause an irruption in the coating. The method used for cleansing steel and iron articles is as follows. They are first boiled in caustic alkali to free them from grease; they are then mechanically cleaned with fine flour emery and brushes in water; they are then brushed with steel wire brushes under a stream of a solution of carbonate of soda; then they are wired and hung in the same solution ready for being made chemically clean. This is done by means of nascent hydrogen in a hot alkaline solution. The water of solution is decomposed on the article by means of a strong current of electricity, the article being made negative. If the solution be kept strong and not carbonised, a film of this solution is sufficient to protect the article from contact with the air in its quick transit from the last purifying process to the solution wherein it is to be coated. The time for it to be transferred can easily be seen by the experienced eye; the article assuming gradually a more silvery appearance. After the proper amount of metal is put on in the coating bath the articles are taken out and washed and dried. The amount of metal put on is ascertained by having a test-surface put in with the articles, and the exact time of putting in and the exact weight of the test noted, and this test is carefully weighed from hour to hour till the amount desired is put on. After being dried, the articles are put into the furnace to have the silver or other metal driven into the surface of the coated metal. The firing furnace, as it is technically called, is of simple construction. The conditions to be observed in its construction are two, namely to obtain a bright red heat in the chamber where the articles are put, and to secure the articles from coming in contact with the fuel or products of combustion. In firing knives-blades and other cutting instruments care has to be taken that they are not carried higher than

between 450° and 500° F. This is ascertained by trials on a pad of prepared test paper; a blade is taken out from time to time and tried upon the pad and the colour is noted—whether it scorches it straw-colour, yellow, pale brown, deep brown, or black. Alum-water is used for regulating this paper as to the colour for the proper degree of heat. After the proper heat is attained the blade is instantly quenched point downwards in cold water and all that were in the firing chamber with it. For articles that do not require tempering or that are made of metal that will not temper, as iron, copper, good brass, or German silver, the heat may be higher. Even if a steel article should be carried so high as to soften it, it can be re-hardened and tempered with the silver or other metal upon it, without in any way injuring the coating. The theory of this part of the process which is technically called "burning in," is this. The coating metal in all cases is one of the superior metals as compared with the coated metal, and is less porous whether cold or hot.

The article being heated, it naturally expands and becomes more porous, as of course both article and coating do, but their relative porosity remains the same, consequently on expansion there will be an infinite number of small cists into which by atmospheric pressure the coating will be driven on attaining the proper heat. Then on the instantaneous quenching in cold water, the coating is seized and retained by the suddenly contracting under metal. This is seen to be the case on filing or grinding the coating off the under metal; for though the coating may be filed or ground off till both coating and under-metal are filed or ground off together, yet the under-metal remains spotted all over with an infinity of little points of the coating metal.

Whitehall, July 3, 1872.

ANALYSIS OF POTASHES.—METHOD OF M. O. HENRY. By F. HAMEL.

THE alkalimetric test of commercial potashes gives, as is known, by alkalimetry, the amount of carbonate of potassa contained, when this salt is not mixed with anything but insoluble substances or with other salts of potassa; but it in no way indicates the amount when they are mixed with soda. In order to discover in this case the potassa, and to estimate it, M. O. Henry has proposed the following process, to which he gives the name *Potassimetry*.

This process depends on the property, which potassa possesses, of forming with perchloric acid a salt completely insoluble in alcohol, while the corresponding soda salt is soluble. This last is therefore used as a reagent for precipitating the potassa. It is procured as follows:—

Chlorate of potassa is heated carefully in a platinum dish until the disengagement of oxygen ceases, and dissolved in twenty times its weight of boiling water; filtered through muslin, and allowed to cool, meanwhile stirring to render the crystals small. The perchlorate of potassa is deposited in small white grains, which are washed with a little cold water, and dried in the air-bath. It is afterwards reduced to a fine powder, placed in a large test-tube, in the bottom of which has been put some mercury, and 5 to 6 parts of pure water added. On one side is placed, in a sandstone retort, a mixture of two-thirds fine, clean sand, and one-third of a mixture of fluor-spar and sulphuric acid in the proportion of one to three; an exit tube is fitted to the neck of the retort, the extremity of which tube dips under the mercury in the test-tube. The retort is then heated, hydrofluosilicic acid is disengaged, which passes through the mercury, and reacts on the perchlorate of potassa, forming a gelatinous hydrofluosilicate of potassa, which is insoluble, and freeing the perchloric acid. The reaction being

finished, the magma produced is thrown into a linen carretlet, washed with distilled water, and the wash-water saturated with crystallised carbonate of soda. It is then filtered, concentrated on the sand-bath to a syrupy consistency, diluted with about its weight of alcohol of 37°, heated gently, and filtered. By evaporating carefully the alcoholic solution of perchlorate of soda thus obtained it furnishes white, needle-shaped crystals, from which is prepared, as we shall see further on, the solution for titrating.

The instrument used by M. Henry for titrating the potassa is made thus:—

A glass tube, about 60 c.m. long and 4 m.m. in diameter, surmounted by a glass cap and terminated by a small faucet, affords a sort of burette, divided into 100 equal parts. This apparatus is borne on a foot, which serves as a support for the apparatus, but which is sufficiently high to allow a beaker glass for precipitation to be placed under the faucet. The pipette, throughout its 100°, is filled with a solution of titrated perchlorate of soda, representing, for each degree, one-hundredth of pure carbonate of potassa. This strength is readily obtained; for this purpose the amount of alcohol of 37° contained in the space of the tube, between 0° and 100°, is run from the tube, and its exact weight taken. Then 10 or 100 times the weight of that quantity of alcohol of 37° is taken, in a graduated flask, and to it is added 10 or 100 times 0.884 grm. of dry perchlorate of soda, which correspond to 1 grm. of pure carbonate of potassa.

We will now describe the working of the potassimetric test. Specimens are taken from various parts of the cask of potash to be tested, to the amount of 250 or 300 grms.; these are mixed, and reduced to a powder as quickly as possible. From this powder 50 grms. are taken, which are treated in the cold with 100 grms. of distilled water. The solution is carefully filtered, and the solution placed in a test-glass graduated into 50 equal parts.

1st. By means of a graduated pipette, 10 measures of this solution, representing 5 grms. of the potassa to be tested, are taken, and subjected to the alkalimetric test, and the alkalimetric degree obtained is noted.

2nd. One measure of the above solution, representing 1 grm. of the potash to be tested, is taken; this is saturated with acetic acid, a slight excess being added, the solution evaporated nearly to dryness, and the residue treated in the cold with alcohol of 37°, then filtered without anything being lost; the alkaline sulphates, chlorides, and silicates remain on the filter. To this liquid, representing in acetate the carbonate of potassa, and that of the soda in the potash under examination, is added, drop by drop, the titrated solution of perchlorate of soda, so long as a precipitate is observable, adding it very slowly, as the level of the liquid in the tube approaches the fortieth and fiftieth graduation. This number indicates, for 1 grm. of the potash examined, the hundredths of pure carbonate of potassa.

On considering on one side, by application of the alkalimetric test, the quantity of sulphuric acid which this potassa saturates, it is easy to arrive at the determination of the proportions of carbonates of soda and potassa mixed together. In effect 100 measures of the alkali-meter represent—

	Grms.
Sulphuric acid at 66°	5.423
Anhydrous sulphuric acid	4.429
Which is equivalent to pure anhydrous KO ₂ CO ₂	7.600
Which is equivalent to pure anhydrous NaO ₂ CO ₂	5.740

On the other side, by means of the potassimeter, the real amount of carbonate of potassa in 100 parts has been determined.

Since this amount should require of actual sulphuric acid the difference between the entire amount of this acid employed in the alkalimetric test and the amount corresponding to the carbonate of potassa determined by the potassimeter, this will give at once the carbonate of soda added, and the double problem will be solved, *i. e.*,

the determination of the real amount of potash present, and the proportion of carbonate of soda added.

Let us take an example to facilitate the understanding of these facts.

100 grms. of commercial potash, taken as stated, giving—

1st. By the alkalimetric test, a number of degrees representing actual anhydrous sulphuric acid, 38.9 grms.

2nd. By the potassimetric test, a number of degrees representing carbonate of potassa, 50 grms.

We have 28.9 anhydrous sulphuric acid for the 50 of pure carbonate of potassa.

The difference, 10 of acid, will represent pure carbonate of soda, 13.3 grms.—*Revue Hebdomadaire de Chimie.*

MILK ANALYSIS BY THE AMMONIA PROCESS.

By J. ALFRED WANKLYN.

THE ammonia process, which Chapman, Smith, and myself applied to water analysis in the year 1867, is available for a great variety of purposes. There is a very simple application to the analysis of milk, which I propose to describe on the present occasion.

In our little book on water analysis, we gave the proportion of "albumenoid ammonia" yielded by caseine as 7.6 per cent. As we remarked, we could not guarantee the absolute purity of the caseine employed for that determination. Recent experiments, however, do not greatly modify the result. Apparently, the number was given a little too high, 6.5 being more in accordance with my later experiments. Inasmuch as normal milk contains 4.0 per cent of caseine, 100 parts of normal milk should give 0.26 part of "albumenoid ammonia," and such is the result of recent determinations.

In order to examine milk by the "ammonia process," the following method of procedure may be adopted. The milk is first diluted to a convenient degree; 5 c.c. (or, preferably, 5 grms.) of milk are placed in a 500 c.c. measure, which is filled up with water to the 500 c.c. mark; the milk and water being then well mixed up together, there results a diluted milk. This diluted milk is of such a strength that 1 c.c. contains 10 milligrammes of milk. For the analysis, 50 milligrammes of milk—i.e., 5 c.c. of the dilute milk—is a convenient quantity.

A tubulated retort, capable of holding about a litre, is charged with 400 c.c. of ordinary water of fair quality, such as, for instance, the ordinary river water supplied by the London water companies. Next, then, is poured into the retort 50 c.c. of alkaline solution of permanganate of potash, made by dissolving 200 grms. of solid caustic potash and 8 grms. of crystallised permanganate of potash in one litre of water. The retort is then connected with a Liebig's condenser, by means of a small piece of wide india-rubber tube, and heated by means of a good-sized Bunsen lamp, the naked flame of which may be applied directly to the retort. Distillation then proceeds. The distilled water, as it comes over, should be tested for ammonia by the Nessler test, in the manner about to be described, and by the time 200 c.c. have distilled over, will be found to be quite free from ammonia. This point having been arrived at, the 50 milligrammes of milk (5 c.c. of dilute milk) are introduced into the retort, which will then contain 250 c.c. of water, 10 grms. of potash, and 0.4 gm. of permanganate of potash. The distillation is then proceeded with as long as ammonia comes over, the ammonia being estimated by the Nessler test.

The measurement of ammonia by the Nessler test is managed as follows:—

A solution of iodide of potassium, saturated with biniodide of mercury, is first prepared thus:—35 grms. of iodide of potassium, 19.1 grms. of bichloride of

mercury—are dissolved in less than a litre of water, heat being employed to assist the solution of the salts. It will be found that a slight excess of biniodide of mercury will remain undissolved—filter or decant so as to separate this small quantity of undissolved red iodide of mercury. (Should, through failure to have used the proper proportion of the salts, there be no excess of undissolved iodide of mercury, a little bichloride must be added, until the red precipitate begins to be permanent). Add, then, either 120 grms. of solid caustic soda, or 160 grms. of solid caustic potash. Dilute the liquid with water to the volume of a litre, and this is the *Nessler reagent*. Before using the *Nessler reagent*, add about 5 c.c. of strong aqueous solution of corrosive sublimate, which will occasion a slight precipitate; decant off this precipitate, and the clear liquid is fit for use. This last addition of corrosive sublimate has for its object the rendering of the Nessler reagent sensitive.

Use of the Nessler Reagent.—Into a cylinder made of colourless glass, and marked so as to be a 50 c.c. measure, put the distillate which you desire to test for ammonia. Add 1½ c.c. of Nessler reagent, which will produce a yellowish-brown colouration. Observe the depth of the colour. On a white piece of paper, side by side with the cylinder containing this coloured liquid just mentioned, place a second 50 c.c. cylinder. Into this second cylinder put pure distilled water, and add to the pure distilled water some standard dilute ammonia liquid—as many measures of the standard ammonia as you judge to be requisite. Add 1½ c.c. of Nessler reagent—a colouration will result—compare the colour with the colour of the liquid in the first cylinder. If the colours are equal, write down the quantity of ammonia you have added, and that will be the quantity contained by the 50 c.c. of distillate. If the colours are not equal, make another trial with a different quantity of standard ammonia, and so on until you get equal colouration.

The strength of the standard ammonia is such that 1 c.c. contains 1-100th milligramme of ammonia. It is made by dissolving 0.315 gm. of chloride of ammonia in one litre of distilled water, and then mixing that solution with nine times its volume of pure distilled water.

The operation of Nesslerising, as it is called, that is, the operation just described, is not difficult, as the many chemists who are in the habit of practising it have abundantly testified. There are a few little points requiring attention; thus a few minutes must be allowed to elapse before reading off the colour: the liquid must be cool, the distilled water must be very free from ammonia, &c. The distilled water used for Nesslerising is best prepared by the operator himself. A fair river water being taken, is set to distil; at first ammoniacal water will distil over, but after a time water free from ammonia will distil, and this must be tested, and then carefully preserved for use.*

The following are some examples of milk analyses by the ammonia process:—

Milk yielding 12.92 per cent of solids and 8 per cent of cream.

	Quantity of Milk taken.	Quantity of NH ₃ obtained.
Exp. I.	100 milligrammes.	0.27 milligramme.
Exp. II.	50 "	0.13 "
Exp. III.	50 "	0.13 "

Milk which appeared to have been somewhat skimmed, but not watered. Solids, 11.42 per cent.

	Quantity of Milk taken.	Quantity of NH ₃ obtained.
Exp. I.	50 milligrammes.	0.135 milligramme.
Exp. II.	100 "	0.255 "

Slightly-watered milk. Solids, 10.20 per cent.

	Quantity taken.	Quantity of NH ₃ obtained.
Exp. I.	50 milligrammes.	0.095 milligramme.
Exp. II.	50 "	0.095 "
Exp. III.	100 "	0.220 "

* For further details, I would refer to the book on Water Analysis, by Chapman and myself.

Highly-watered milk. Solids, 6·18 per cent.
Quantity taken. Quantity of NH_3 obtained.
Exp. I. 50 milligrammes. 0·075 milligramme.

Highly-watered milk. Solids, 8·10 per cent.
Quantity taken. Quantity of NH_3 obtained.
Exp. I. 50 milligrammes. 0·070 milligramme.

Expressed in a tabular form:—

	Per cent. Solids in Milk.	Per cent. of Ammonia.
I.	12·92	0·27
II.	12·92	0·26
III.	12·92	0·26
I.	11·42	0·27
II.	11·42	0·255
I.	10·20	0·19
II.	10·20	0·19
III.	10·20	0·22
I.	6·18	0·15
I.	8·10	0·14

In order to translate these results into percentages of caseine contained by the different samples of milk, it has to be borne in mind that 6·5 parts of ammonia correspond to 100 parts of caseine. The ammonia, therefore, when multiplied by 100 and divided by 6·5 indicates the caseine. In conclusion, the ease and rapidity of these determinations may be referred to. In half an hour an analysis of milk by the ammonia process may be easily made.—*The Milk Journal*.

ON THE EVIL EFFECTS OF THE USE OF ARSENIC IN CERTAIN GREEN COLOURS.*

By FRANK W. DRAPER, M.D.

EVERYBODY knows that arsenic is a deadly poison. Its name at once suggests to the popular mind a virulence of action possessed by only a few of the kindred agencies which are placed at the disposal of mankind. Although recognised by the physician as a valuable remedy under certain conditions, its administration is advisedly attended with special caution, its minimum dose being fixed at a very small fraction of a single grain. Murderously-disposed men have found it a quick and subtle means for the accomplishment of their malicious purposes; and discontented mortals, tired of life, have taken it as an efficient instrument for self-destruction. In acknowledgment of its deadly power, wise legislative enactments have prudently regulated and restricted its sale by druggists and others, with a view to protect mankind, as far as may be, from the evil effects of its indiscriminate distribution.

In contrast with this general knowledge of the poisonous properties of arsenic, and with the carefully devised measures which are enforced in order that the least possible harm may result from the employment of such an agent, is its unrestricted use in certain arts, and in the manufacture of certain articles which, by most persons, are deemed harmless. The application of arsenic as an ingredient in certain pigments is very extended. It finds its way thus into our dwellings is spread on the walls of sleeping rooms, is worn in articles of dress, and assumes a great number of forms in which its presence is unsuspected, or, if recognised, is not deemed deleterious. It is the object of this paper to point out some of these forms in which arsenic is introduced to daily use, and to inquire if this liberal exposure is productive of harmful results.

† The investigation is not an original one. At various intervals during the whole of the present century, attention

has been called to the subject by scientific observers; strong warnings have been given of the danger which was believed to be entailed, and earnest appeals made for some effective legal measures of restriction or of prohibition. So long ago as 1740, the employment of arsenic as a pigment in certain manufactures was forbidden in France, and attempts have been made from time to time since then to regulate trade in this respect. These warnings and enactments have, however, proved but partially effectual; and it is believed that at the present day the subject is one which warrants solicitude in behalf of the public health, and justifies renewed investigation by its continued magnitude.

Arsenic, aside from its utility as a remedial agent, is chiefly employed to form an ingredient of certain green colouring matters. It enters into two of these pigments—the arsenite of copper, which is Scheele's green, and the aceto-arsenite of copper, called also Schweinfurt green, from the town where it is largely manufactured. To both of these names are, moreover, given interchangeably, and they are generally known among workmen as emerald green or "emerald," mineral green, sometimes (although erroneously) as Brunswick green or Vienna green. In France, they are called *vert Anglais*, or English green. Of these colours, the former (Scheele's green) contains more than one-half its weight (55 per cent) of pure arsenious acid, or white arsenic; while the Schweinfurt green is still more abundantly supplied, having, in 100 grains, 58 grains of the poison.

Either of these combinations of arsenious acid and sulphate of copper forms a very beautiful and durable green colour whose brilliancy will bear any light well. Its tint is a lighter and purer green than any other of artificial manufacture, and hence is especially alluring to the eye. The materials of which the pigments are made are comparatively inexpensive, and the manufacture involves very little intricacy or delicacy in its various processes. For these reasons, these arsenical greens have always maintained their popular favour, both with manufacturers and the public in general. Their use has been, and still continues to be, extensive and lucrative, giving employment to large numbers of workmen. So important has their application been considered in the making of wall-paper and of artificial flowers in Paris, that when, at one time, it was agitated whether it were practicable to prohibit the use of arsenic in these arts, certain of the manufacturers protested that such an edict would necessitate the absolute suspension of their works. In 1860, a manufacturer of paper-hangings in England stated that he used 2 tons of arsenic weekly;† and the amount of the colour annually manufactured in England was estimated in 1862 at from 500 to 700 tons.†

It should not be inferred from these statements that all green pigments in ordinary use are arsenical. Not a small proportion of the green colours employed for painting, dyeing, or colour printing are of other and comparatively harmless composition. It is not always easy to distinguish them by their physical appearances, but chemistry affords a ready test which may be easily applied. The suspected green material is to be placed in a solution of ammonia. If arsenite of copper be the colouring agent, the liquid will acquire a blue tint, owing to the disengagement of the oxide of copper from its combination with the arsenic. If a further test be desired, a few drops of the coloured ammoniacal solution poured upon crystals of nitrate of silver will leave on the crystals a deposit of yellow arsenite of silver.

These arsenical green pigments are both deadly poisons, differing in the intensity of their effects only in slight degree from the pure arsenic of which they are in part composed. Taken into the stomach, they give rise to the same train of symptoms and demand the same prompt antidotes. The combination of the arsenious acid with

* From the "Third Annual Report of the State Board of Health of Massachusetts."

† "Fifth Report of Medical Officer of Privy Council," 1863, p. 129.

copper serves only to dilute the poisonous properties of the former, and offers no farther protection against its action. Suicides have availed themselves of the pigment as a means of self-destruction. In 1849, a girl, aged 12 years, a maker of artificial flowers, became possessed with a distaste of life remarkable at her age. She swallowed a quantity of the arsenical green powder used in her work; symptoms of acute arsenical poisoning promptly supervened, and in spite of remedies, vigorously applied, the girl died in a few hours.

Such are the properties of the green colouring matters containing arsenic. It remains to study some of the forms under which they are presented to the public, with the dangers pertaining to their indiscriminate employment.

1. *Artificial Flowers and other Articles of Dress.*—The manufacture of artificial flowers constitutes an important and extensive industry both in this country and abroad; and into some of its various branches the employment of the arsenical greens has largely entered. Many of the green sprays of artificial grass and leaves which so closely imitate the verdure of nature and bring out in artistic contrast the floral colours with which they are combined, owe their delicate shade and brilliancy to the presence of emerald green.

The process of manufacture is a simple one. Generally, the texture from which the leaves are to be cut is coloured in the piece. The colouring material is made by thoroughly stirring together a mixture containing, in definite proportions, the green pigment, cold water, and starch, gum-arabic, or some similar substance which shall give the colour consistence and adhesiveness. Not unfrequently, in this process, the hand and fore-arm are freely used in the liquid, to expedite the work. Of this mixture, properly prepared, the workman takes a quantity in his fingers, and roughly spreads it over the muslin or fine calico. The fabric is then beaten and kneaded between the hands until it is uniformly coloured; the longer this process is continued the more perfect is the result. The cloth is now fastened to a frame for drying. In all this process of colouring, the hands, fore-arms, and frequently also the face of the operative must become soiled with the green colour. It will be also observed that the colour is but loosely applied, no mordant being used, as in calico-printing, to fix the pigment in the texture of the cloth.

In the various subsequent processes of cutting, stamping, shading, and mounting, to which the material must be subjected before the plain cloth becomes the artificial leaf, the arsenical green which is used to produce such a close resemblance to natural verdure inevitably escapes in greater or less abundance, and mingles with the ordinary dust of the apartments in which the manufacture is carried on. Moreover, some of the special methods which are employed to perfect the work promote the dissemination of the powder: thus, in the operation called "fluffing," which consists in dipping the leaf into warm wax and immediately dusting the dry colour upon it from a dredging-box, the workman is particularly exposed to the effects of the freely-floating particles. All the manipulations, in short, subject the material to varying degrees of violence, by which the arsenical powder is detached. This powder is inhaled by those exposed, and the precaution sometimes employed of placing towels or other masks before the mouth and nostrils cannot furnish absolute protection to the wearers. The moist skin attracts the dust, and the clothes give it lodgment. The soiled hands are not often perfectly cleansed before they are used to convey food to the mouth, and an additional source of risk is thus provided.

The quantity of arsenic which, in the various processes of their manufacture, these artificial leaves are sometimes made to take up would appear almost incredible. Careful chemical analysis has determined this amount repeatedly. Hofmann found, in a single twig of twelve leaves, 10 grains of pure arsenic. A lady might thus

carry, in all innocence, to an evening party enough arsenic in her floral adornments to destroy herself and a score of her fellow guests.

The effects which exposure to the arsenic contained in artificial leaves may produce, either in those engaged in their manufacture or in those who use them, have been renewedly made the subject of careful investigation. Intelligent and impartial scientific observers in France, Germany, and England do not hesitate in declaring the pernicious influence of continued exposure to such conditions, and numerous instances are cited to demonstrate not only harmful, but occasionally fatal effects. An investigation was made by M. Vernois, in 1859, concerning the accidents resulting among the flower makers of Paris from the use of arsenical greens, and, as the result of his researches, he points out many symptoms which, he believes, may be directly traced to arsenical infection. Among these are included various eruptions on the skin, presenting sometimes a papular form, sometimes vesicular, sometimes a simple diffused redness (erythematous), and sometimes developing to ulceration and gangrene, the seat of the disease being preferably those parts exposed most directly to the irritant action of the poison, as, for example, the hands and face, the former especially presenting ulcerations if the colour enters cuts or abrasions. Along with these external symptoms are loss of appetite, nausea, colic, continued headache, pallor, and debility.* Dr. Hassall, writing in England at about the same period, in describing one of his visits to a manufactory of artificial flowers in London, states:—

"In the same room were two men, eight women, and two boys, the condition of all being wretched in the extreme. They were all similarly affected. They all had sores; the girls, at the back of the neck, on the sides of the nose, and on the hands; their eyes were also affected, and there was running from the nose. To such an extent was their health affected that they were obliged from time to time to give up their work and return home."†

Dr. Hillier, too, investigated the condition of the London flower-makers in 1861, and found that they "suffered from chronic inflammation of the stomach and bowels, irritation of the eyes, great nervous debility and prostration, with local irritation of the skin of the hands, neck, and scalp when the powder was brought into contact with, and allowed to remain on, those parts."‡ Several workpeople stated that they were constantly ill while working with this powder.†

But besides these generally acknowledged symptoms of chronic arsenical poisoning, as manifested in these people after working continuously with emerald green, still more serious results are possible, and cases are recorded of fatal effects upon specially susceptible organisms. The following is illustrative:—In 1861, a girl, aged nineteen years, who had been engaged continuously during eighteen months in making artificial flowers with emerald green, died in London with all the characteristic symptoms of chronic poisoning by arsenic. Her sufferings were very greatly intensified towards the close of life. Examination after death discovered the very evident presence of arsenic in the internal organs.||

These exceptionally fatal cases bear very small proportion, it is true, to the numerous well authenticated instances of less serious results which are notorious among the operatives themselves as arising in their vocation. This is explained partially by the fact that such fatalities might readily be ascribed to other causes, supposing them to occur more frequently, while, on the other hand, it is obvious that persons exposed to such a noxious influence would probably desist from this work long before the symptoms were serious enough to threaten a fatal termination.

But not only do the operatives, who in making the

* *Annales d'Hygiène*, and ser., tome xii., p. 379. ‡

† *Lancet*, 1860, p. 535.

‡ "Fifth Report of Medical Officer of Privy Council," 1862, p. 126.

|| *Medical Times and Gazette*, Nov. 30, 1861.

artificial flowers use the arsenical greens, suffer in proportion to their susceptibility and exposure, but in many cases also those who wear them, and those who, like shopkeepers and milliners, habitually handle them. A case is reported of a clerk who always had vertigo, headache, nausea, and cough whenever he opened and handled new packages of green artificial foliage.* In another instance which is recorded, a lady's shoulders became the seat of a painful eruption directly after each occasion of wearing a wreath of artificial flowers and leaves at evening receptions; and, in two other reported cases, an erysipelatous eruption on the forehead was traced to a similar cause.† The physicians to some of the large London hospitals have expressed themselves as familiar with "the inflamed eyes and disfiguring eruptions," which, as they assert, result from the use of the arseniferous verdure.

It is obvious that of such cases only the most remarkable and clearly defined would be reported; and we may reasonably infer from these that many less distinctive instances really occur. It is not unreasonable to suppose, for example, that the health of milliners, proverbially delicate as a general thing, may depend for its deterioration to some extent upon this factor, as well as upon overwork, crowded and ill-ventilated rooms, and insufficient exercise. It is bad enough to inspire an ordinarily foul atmosphere, but it can certainly add nothing to atmospheric purity to mingle with the dust of a room any proportion, however small, of oxide of copper or of white arsenic.

Closely related to the foregoing topic, is the use of the arsenical green pigment in the manufacture of other articles of dress; and among these the material called tarlatane, a light fabric resembling muslin, has attracted much attention. The mineral green with which the material is coloured recommends itself because of the brilliancy of its shade and of its permanency by artificial light; and the fabric has therefore at times been quite fashionable. A considerable quantity of it is still sold for dresses, or for the trimmings used by milliners. It is known popularly as an "arsenical" green, so that its character is not altogether unrecognised.

In the manufacture of this material, the colour is fixed only by starch or size, and when tarlatane is torn, a plentiful cloud of light green arsenical dust arises. The slightest agitation also serves to disengage the coloured powder, and to diffuse it through the adjacent air. It is easy to discover how readily the wearer of one of the expansive dresses prescribed by fashion might under certain circumstances surround herself with a cloud of poisonous dust of whose effects on herself and on those about her she would be unhappily ignorant.

The arsenical-green tarlatanes contain nearly half their weight of colouring matter. A sample, procured by the writer in one of the retail stores of Boston, was analysed quantitatively by Prof. William Ripley Nichols at the Massachusetts Institute of Technology, and found to contain 8.21 grains of arsenious acid (white arsenic) to each square foot. A dress of ordinary dimensions would thus hold feebly in its texture between three and four ozs. of pure arsenic.

It would not seem probable that the occasional wearing of such a material would produce symptoms of serious harm to either the wearer or to those around her, the noxious exposure in such cases being limited in time and degree. Yet instances are not wanting to demonstrate its deleterious effects on those engaged in making the fabric into dresses. In one case, reported by Chevallier, five dressmakers were more or less seriously affected after working on the tissue.‡ Two years ago a similar instance of poisoning occurred in France, where arsenical greens are prohibited by law; and the dress was found to contain

nearly eight ozs. of arsenic.* On one occasion, where a new ballet was performed at Hamburg, the dancers who represented water nymphs, were dressed in green tarlatane. These dresses "nearly cost the lives" of those who made them, and of those also who wore them. So large was the quantity of arsenic in the fabric that nearly all were more or less poisoned.†

In 1869 a case of poisoning from the cause under consideration occurred in Boston, the details of which were given to the writer by one of the persons affected. Four dressmakers, while engaged upon some party dresses of which the material was arsenical green tarlatane, became simultaneously affected with well-marked symptoms. These symptoms consisted of swelling of the hands and face, a "pimply" eruption on the back of the hands and about the nostrils, running from the nose, and free lachrymation. With these local effects were headache, lassitude, and a feeling of general illness. The attack coming on in the midst of perfect health, and affecting all but one of those who worked upon the arsenical fabric, left little doubt in the minds of the sufferers of the nature of the poison. The symptoms subsided as soon as the exposure ceased.

(To be continued).

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.‡

By Dr. F. CRACE CALVERT, F.R.S.

(Continued from p. 20).

Red Colouring Substances (continued):—Munjeet; Campechy, Peach, Sappan, Cam, and Bar Woods; Alkanet Root; Safflower; Cochineal, Lac-Dye; Murexide.

Munjeet.—It is to the researches of Dr. John Stenhouse, one of the most eminent and learned of English chemists, that we are indebted for our knowledge of the true composition of many of the dye-stuffs, and it is to him that we are indebted for the whole of the information we possess in the colouring matters of munjeet, or *Rubia Munjistia*.

This peculiar variety of the genus *Rubia* is cultivated exclusively in Asia, and especially in India, where it has been used as a dye-stuff for a long period of time, either alone or mixed with other dyes, to produce a variety of red shades. It is imported into this country from time to time, but has never been extensively used, as the colours produced from it are neither so fast nor so bright as those obtained with *Rubia tinctorum*.

Whilst the colouring principles of madder are purpurine and alizarine, those of munjeet are purpurine and a yellow colouring matter, named by Dr. Stenhouse munjistine. He has assigned to this latter body the formula $C_{16}H_5O_6$. When crystallised from an alcoholic solution, it forms large, beautiful, golden-coloured flakes, which sublimed, give prismatic crystals, of an orange-red colour. It is only slightly soluble in cold water, but freely soluble in hot water. Its best solvent is bisulphuret of carbon, which was employed with success by Dr. Stenhouse in separating the purpurine and munjistine from the other substances existing in munjeet. He states that the munjeet root contains as much colouring matter as the *Rubia tinctorum*, and, according to Mr. Higgins, of Manchester, it yields from 52 to 55 per cent of a garancine; but as it has only half the dyeing power of ordinary garancine, it cannot be employed with advantage for this purpose. The inferiority of munjeet arises from its containing only the comparatively feeble colouring matters, purpurine and munjistine. Munjeet is not much used by calico-printers,

‡ The Cantor Lectures, delivered before the Society of Arts. Revised and communicated by the Author.

as the munjistine gives a brownish-purple with salts of iron, which prevents it being employed with that mordant. It is used for special shades of Turkey-red, the munjistine giving, with salts of alumina, an orange-yellow colour, which is in some instances employed by the dyers.

I have now the pleasure of calling your attention to an important class of dyeing substances, "the dye-woods."

Campechy or Logwood.—This wood, obtained from a large tree of the leguminous family, called by the botanist *Hematoxylon campechianum*, grows abundantly in the West Indies, Mexico, and other states of South America. The best quality is imported from the Bay of Campechy, in the Gulf of Mexico. Large quantities are also obtained from Jamaica and St. Domingo. The qualities obtained from Honduras, Martinique, and Guadeloupe are inferior.

Campechy was introduced into Europe by the Spaniards, but it was not till the reign of Elizabeth that it came into use in England, and then only for a short period, after which its employment was forbidden under the severest penalties for upwards of a century.

The discovery of its colouring principle, hematine, was made in 1810, by my learned and venerable master, M. Chevreul (who, although now 85 years old, is still actively engaged in scientific pursuits). Shortly afterwards it was studied by Ermann, who gave it the name of hematoxyline. It was obtained by these eminent chemists as yellowish white prismatic crystals, which become discoloured by contact with the oxygen of the air and the small amount of ammonia which the atmosphere contains. It is only slightly soluble in cold water, but much more so in hot. It is very soluble in alcohol, ether, and bisulphuret of carbon. It combines with three equivalents of water, forming a crystalline hydrate, which at 212° F. retains one equivalent.

Hematine in the presence of oxygen, especially under the influence of alkalis, assumes a beautiful purple colour. This colouring matter can be obtained under the form of purple-black crystals, having a metallic lustre, and has received the name of hematine. Hematine has the formula $C_{16}H_{14}O_6$, which, on conversion into hematine, becomes $C_{16}H_{12}O_6 \cdot H_2O$. The hydrate is $C_{16}H_{14}O_6 \cdot 3H_2O$, which at 212° F. becomes $C_{16}H_{14}O_6 \cdot H_2O$.

The oxidation, and consequent colouration, of hematine under the influence of oxygen and alkalis is so rapid that it may be used as a most delicate test of the presence of carbonate of lime in natural waters; and it is a fact well known to practical dyers that waters containing a large quantity of carbonate of lime are well adapted for the production of good logwood blacks. Hematine gives little or no colouration with salts of protoxide of iron, but hematine gives a dark purplish blue; the latter also gives dark blue precipitates, with salts of lead and tin. Hematine is easily reduced to hematine by hydrogen and sulphuretted hydrogen.

In my opinion, the colouring matter in *Hematoxylon campechianum* exists in the state of a glucoside, for when the trees are felled the wood is colourless; but by the time the logs arrive here the outside is of a dark red colour, whilst the inside has only become of a pale yellow colour.

As hematine is the principle which the dyer requires, the logs are ground into a coarse powder, which is moistened and laid in beds 15 or 20 feet long by 10 or 12 broad, and about 3 feet thick. A slow fermentation ensues, by which the glucoside is decomposed and the hematine liberated. It is converted into hematine by stirring the mass, thus exposing it to the oxygen of the air, the action being quickened by the ammonia of the atmosphere as well as by that given off by the decomposition of the azotised principles existing in the wood.

This prepared wood is used by the dyer to produce logwood blacks, as I shall describe further on, and also by wood extract manufacturers, who prepare an extract which

is much used in calico-printing. To prepare this extract it is necessary that the wood should not be too highly oxidised, and that the solution obtained from it by successive and repeated lixiviation should be slowly concentrated at a comparatively low temperature, that is to say, not exceeding 150° F.; for if a high temperature be employed the hematine is still further oxidised, and a dark purple resinous principle produced, which spoils the brilliancy of the colour.

This extract is chiefly used in print works, to produce purples in steam styles.* A strong logwood solution is thickened with starch, and printed on a prepared cloth; that is, a cloth that has been passed through a solution of stannate of soda, then through weak vitriol, by which means the binocide of tin has been fixed as a mordant in the fibre of the cloth; the fabric after washing and drying, is ready for the printer. After being printed, the cloth is either rolled on a perforated cylinder or hung in an iron chamber, and submitted to the action of steam, when the hematine combines with the oxide of tin, producing a beautiful purple.

If blacks are to be produced, an iron mordant is fixed on the fabric, which is then passed through a logwood solution. It is afterwards washed, and the black fully developed by passing it through a hot dilute solution of bichromate of potash.

Logwood and its extract are much used in Yorkshire for producing cheap blacks on mixed fabrics, which are goods in which the warp is cotton and the weft woollen. The black is produced by dyeing the fabric in a bath composed of logwood, sulphate of soda, and bichromate of potash.

It is often very useful to distinguish logwood blacks from sumach and other fast blacks, and logwood purples from aniline purples. This is easily effected by submitting the piece to the action of weak acids; the logwood colours assume a bright red tint, while the others remain unchanged.

Brazil Wood.—We shall now pass on to a series of woods which are all obtained from the genus *Casalpinia*, belonging to the natural order *Leguminosae*.

Although these woods have long been employed as dyes by the natives of the countries where they grow, it is only since the introduction of Brazil wood by the Spaniards, that their value as dye-stuffs has been known in Europe. The best qualities are all imported from Brazil. The particular wood known as Brazil wood, derived from the *Casalpinia brasiliensis*, has become scarce in the market, from its having been all cut in the districts within easy distance of shipping ports.

The wood most in favour at the present day comes from Pernambuco, and is the *Casalpinia Crista*. This tree is also found in Jamaica. That obtained from Sierra Nevada is not of such good quality.

Another variety, bearing the name of peach-wood, is chiefly derived from Nicaragua. A third, known as Sappan-wood, comes principally from Siam, the East Indies, and other eastern countries. A rather inferior quality, known as Lima-wood, is imported from Peru.

All these woods appear to contain the same glucoside, and, like the previous ones, are decomposed by peculiar ferments, into a saccharine matter and a colour-giving principle. This is proved by the following experiments. If the decoction obtained by treating the wood from the interior of the sticks be boiled with a solution of double tartrate of potash and copper (the best known test for grape sugar), no precipitate is obtained; while if the glucoside be first decomposed by boiling with a dilute solution of hydrochloric or sulphuric acid, and afterwards treated with the copper salt, an abundant precipitate of suboxide is thrown down. The decoction,

* Calico printers employ the word style or govels when speaking of a class of goods which are denoted by a word characterising the colouring matter used, or the method employed in producing them. Madder goods and garancine styles may be given as examples of the first and steam styles of the second.

which has only a faint yellow colour, gives a most abundant and brilliant precipitate with subacetate of lead. The colour-giving principle was discovered by M. Chevreul, who gave it the name of *braziline*. By oxidation it is converted into *brazilline*. It also combines with water, to form a hydrate containing two equivalents of water. Professor Bolley gives the formula of braziline as $C_{22}H_{20}O_7$, and that of the hydrate $C_{22}H_{20}O_7 \cdot 2H_2O$. He has also made the curious observation that a comparison of the formulæ of hematine and braziline shows a difference equal to carbolic acid, as may be seen by the following table:—

Braziline	$C_{22}H_{20}O_7$
Hematine	$C_{16}H_{14}O_6$

Difference .. $C_6H_6O_1$ Carbolic acid.

What is still more remarkable is, that by the action of nitric acid upon hematine, he obtained oxalic acid, whilst under similar circumstances braziline yields oxalic acid and picric or trinitrophenic acid, which is the product obtained when carbolic acid is acted upon by nitric acid.

A decoction of any of these woods becomes yellow or orange, (according to the quantity of braziline or brazilline it contains) on the addition of an acid, and by the addition of an alkali, a beautiful crimson red, the shade of which varies according to the proportion of the two principles. It also becomes red with bichromate of potash, and gives a red precipitate with oxymuriate of tin.

These characters are sufficient to distinguish between a solution of these woods and one of logwood.

To prepare a good commercial extract from these woods, they must be finely ground, as they yield their colour to water with difficulty; like logwood, they must be allowed to ferment and oxidise in the air, but not to the same extent. The concentration of the decoctions differs from that of logwood in the fact that they can bear a higher temperature. The more quickly they are evaporated the brighter are the colours which the extract gives. Dr. Dingler has proposed a process which is stated to give very good results. It consists in adding 4lbs. of gelatine, dissolved in water, to every cubic yard of ground wood, and allowing the whole to ferment for several days. The wood so treated yields a stronger and richer extract than that obtained by the ordinary process; no doubt the gelatine helps the decomposition of the glucoside, and the ammonia produced facilitates the oxidation of the braziline. By the addition of a small quantity of chlorate of potash to the hot extract, Mr. Peak greatly increased its brilliancy, and rendered it more valuable to the printer on account of the brighter colour produced on the fabric.

These extracts are principally used to obtain pinks and reds in steam styles. To effect this, acetate of alumina, chloride of tin, oxalic acid, or acetate of copper is added to the extract, and printed on the prepared cloth already described, which is then submitted to the action of steam.

These woods are also used in conjunction with a little quercitron, or bark, in the production of cheap garancine styles. These inferior garancine prints are easily distinguished from the good ones by means of a hot soap-bath, which only slightly affects the good, while the inferior are almost entirely destroyed. The woods also are sometimes used for the adulteration of garancine.

I may state, before leaving this subject, that the decoction of these woods yield very beautiful pink lakes, which are principally used by paper-stainers.

Common red ink is also prepared by adding a little alum and acid to an aqueous solution of these woods.

Red Sandal, Cam, and Bar Woods.—The next class of dye-stuffs which we shall have the pleasure of studying together are derived from several varieties of the genus *Pterocarpus*, which are indigenous to the tropical parts of both the new and the old world. It is principally from the East Indies, Ceylon, Madagascar, and the coast of

Malabar, that santal, sandal, or red sanders-wood is imported, whilst cam and bar woods are procured from the West Coast of Africa.

The colour-giving principle of this class of plants is only developed with age, the young branches not containing any, whilst it is found in large quantities in the trunk. Professor Bolley proved that it is the same colour-giving principle which exists in each variety, and he gave it the name of santaline. MM. Wagermann and Haefely consider that it has the formula $C_{15}H_{14}O_5$. It is a bright red crystalline powder, insoluble in water, but soluble in alcohol, ether, and acetic acid. The latter solvent yields the colouring matter to albumen, which is an important fact, and may one day be rendered practically useful. Santaline is freely soluble in alkalies, giving a violet-red solution, from which acids precipitate the colouring matter.

Red sandal-wood is chiefly used on the Continent, where it is employed to give a bottom* to cloth which is to be afterwards dyed with indigo. By this process a very fine blue is produced, having a purple hue by reflected light.

Cam-wood, and especially bar-wood, is chiefly used in England for producing on cotton yarns brilliant orange-red colours, known as mock Turkey-reds. They are, however, neither so fast nor so bright as the real Turkey-red produced from madder, and are easily distinguished from it by yielding their colour to a hot soap solution, or to alkalies.

(To be continued.)

A NEW METHOD OF OBTAINING POTASSIUM.

By Prof. A. E. DOLBEAR.

PERHAPS it is not possible to discover a process for obtaining the metals potassium and sodium better than the one usually employed with the carbonates of the metals and charcoal, heated in iron retorts, but it is a very desirable thing to obtain them cheaply on account of their use in the manufacture of aluminum. As I have been successful in obtaining potassium by a method new to me, the process may have some interest to chemists, whatever may be its commercial value.

Some white stick caustic potash of commerce was dissolved in water and then treated with sulphuretted hydrogen in the way commonly described for making potassium sulphide, K_2S . The solution was evaporated until it was solid when cool, when the yellowish mass was mixed with more than its bulk of iron filings and chips, and the whole put into an alembic for distillation. The heat of a furnace was applied till the alembic was of a bright red heat, and the products of distillation were received in common coal oil. The product was rather small, as some of the potassium vapour decomposed the heated vessel; nevertheless the potassium showed itself when the oil was poured off, and the residuum turned upon water by its characteristic ignition and flame. The reaction is simple and may be thus represented. $K_2S + Fe = FeS + K_2$.

I have not conveniences for experimenting upon this on a scale large enough to test its comparative value; it needs some special arrangements of protected vessels, as it violently attacks common crucibles, porcelain, and glass. The materials used for thus obtaining it are of the required cheapness, and the iron sulphide product can again be used to furnish sulphuretted hydrogen for another quantity.

It is probable that sodium can be obtained by an analogous process, but I have not attempted it.—*American Chemist*.

* This term is used in dyeing, to denote that a colour is applied to a fabric with a view of giving a peculiar hue to a dye which is applied after it.

NOTICES OF BOOKS.

A Manual of Chemical Physiology, including its Points of Contact with Pathology. By J. L. W. THUDICHUM, M.D. London: Longmans and Co. 1872.

To the student in Chemistry and other Sciences Dr. Thudichum's work offers a ready help to the acquisition of elementary knowledge, upon which can be afterwards placed the superstructure of more detailed studies. The manual is divided into two parts, the first having been written as the introduction to the Author's "Researches intended to Promote an Improved Chemical Identification of Diseases," published in several numbers of the annual "Report of the Medical Officer of the Privy Council," and being a concise epitome of physiological or animal chemistry. The second part of the work is an Analytical Guide for the use of Students who desire to become practically acquainted with the constituents of animal bodies. The manual is well illustrated with drawings of spectra; is clearly arranged, and contains more than the usual amount of information, supplying a want amongst medical students.

A New Star Atlas, for the Library, the School, and the Observatory. By RICHARD A. PROCTOR, B.A. (Camb.), F.R.A.S., Author of "The Sun," "Other Worlds than Ours," "Saturn and its System," &c. London: Longmans, Green, and Co. 1872.

THIS admirable little Atlas is a reduction from Mr. Proctor's large Star Atlas, and is intended as a companion to Webb's "Celestial Objects for Common Telescopes." It fulfils a crying want, for we have had hitherto no work directing the student of the heavens to its chief star groups. But this little work is so well arranged, that it includes besides the chief features of the heavens, groups that are unattempted in much more pretentious works. It will well repay packing in the trunk and studying on some starry night during the country vacation tour.

Lecture Notes for Chemical Students. By EDWARD FRANKLAND, D.C.L., F.R.S., Corresponding Member of the Imperial Institute of France, &c., Professor of Chemistry in the Royal School of Mines. Vol. II. Organic Chemistry. Second Edition. London: Van Nostrand. 1872.

STUDENTS of chemistry under the auspices of Dr. Frankland will be glad to learn that a second edition of the "Organic Chemistry" has been published with the additions required by the advancement of synthetical investigation.

Chimie Organique Elementaire. Lecons Professees a la Faculté de Médecine. Par EDOUARD GRIMAU, Professeur agrégé à la Faculté de Médecine de Paris. Paris: Baillière. 1872.

WE are indebted to our French neighbours, and to Dr. Atkinson for one of the best text-books of physical science, and doubtless we shall soon have a translation of this admirable little work from the pen and laboratory of Professor Grimaux, for a better ordered or more complete treatise it would be difficult to find. Written for medical students, the work has not that want of experimental data so common in works on medical chemistry. The modes of preparing the principal organic compounds are fully detailed, their composition considered, and their physiological action explained, while to the latter no undue prominence is given. The work is thus as useful, and perhaps more interesting to the general student of chemistry than the average hand-book, dealing with theory or practice apart; while the information as to the toxic effects of the several substances is not only a valuable but a necessary adjunct. We commend the work, and we cannot do so too highly.

CORRESPONDENCE.

PROPOSED ASSOCIATION OF MANUFACTURING CHEMISTS.

To the Editor of the Chemical News.

SIR,—I have read all the correspondence in your journal as to the organisation of an Association of Manufacturing Chemists, and highly approve of it. No doubt there are many departments of our great staple industry where the varying experience might lead to general benefit without interfering with the specialities of different manufacturers; and the communication of ideas would, as in other important manufactures, lead to improvements that would benefit all. I shall be most happy to afford my small aid to such an institution in any way practicable.—I am, &c.,

PETER SPENCE.

Pendleton Alum Works, Manchester,
July 15, 1872.

To the Editor of the Chemical News.

SIR,—The want of an Association of Chemical Manufacturers is one that I have long felt, as there are many questions affecting the trade that can only be properly ventilated by such a society; among others, I would mention the questions of sampling and chemical analysis. I shall be most glad to forward the scheme in any way, and would suggest that there should be a committee formed who would endeavour to put the matter into a working form. I am convinced that all the principal firms would most gladly co-operate.—I am, &c.,

EDWARD PURSER, JUN.

Plough Wharf, Cubitt Town,
July 15, 1872.

MISCELLANEOUS.

Society of Arts.—Technological Examinations.—His Royal Highness Prince Arthur will preside at a conference on this subject, to be held at the rooms of the Society, in the Adelphi, on Saturday, July 20th, at 12 o'clock. Merchants, manufacturers, and others interested in the movement, are invited to attend.

Quality of Metropolitan Gas.—Dr. Letheby, the chief Gas Examiner appointed by the Board of Trade, has recently reported to the Corporation of the City, and to the Metropolitan Board of Works, on the quality of the gas supplied to the Metropolis by the Chartered, the Imperial, and the South Metropolitan Gas Companies, during the last three months; from which it appears that the illuminating power has never been less than that required by the Acts of Parliament. The common gas of the Chartered Company has ranged from an average power of 16.89 standard sperm candles at the Millbank testing-place, to 17.85 candles at the testing-place at Mile End. The Imperial Company's gas has ranged from 15.72 candles at Camden Street, to 16.85 at Oakley Square, Chelsea; and the gas of the South Metropolitan Company has averaged 15.78 candles. The cannel gas of the Chartered Company has had an average illuminating power of 25.74 candles at Millbank Street, and 26.06 candles at Arundel Street in the Haymarket. With respect to purity, Dr. Letheby reports that the gas at each of the testing-places has been constantly free from sulphuretted hydrogen, but that the fluctuation in the amounts of sulphur have been considerable, as from a minimum of 2.2 grains per 100 cubic feet of gas at Mile End, to a maximum of over 4.0 grains at Beckton, at Cannon Street, at Arundel Street, and at Hill Street, Peckham; the average proportions at the different testing-places having been as follows:—The common gas of the Chartered Company at Beckton 26.98 grains per 100

cubic feet; at Cannon Street 25.77 grains; at Friendly Place, Mile End, 8.71 grains; at Arundel Street, Haymarket, 18.89 grains; and at Millbank Street, Westminster, 26.96 grains; while that of the Imperial Company has been 32.98 grains at Oakley Square, Chelsea; 28.16 grains at Camden Street, Camden Town; and 25.71 grains at Graham Street, Dalston. The average amount of sulphur in the South Metropolitan gas was 36.05 grains per 100 cubic feet. It is a noticeable fact that the quantity of sulphur in the gas of the Chartered Company at Friendly Place has only once contained as much as 20 grains per 100 feet; and that during the last month the gas at Beckton, at Cannon Street, at Friendly Place, and at Arundel Street, has never contained 20 grains per 100 feet; the average for the month having been from 4.63 grains at Friendly Place to 13.64 grains at Beckton. Dr. Letheby regards this as highly satisfactory. The proportion of ammonia in the gas has not at any time or place exceeded the quantity (2.5 grains per 100 cubic feet) prescribed by the referees; the average amount being from nil to 1.28 grains per 100 feet.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, June 24, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

Examination of the Rocks containing Native Iron which were Discovered in Greenland in 1870 by Dr. Nordenskjöld.—M. Daubrée.—This extensive essay treats on the lithology of the large meteorites found in Greenland and transferred to Europe last year. The percentage composition of the blackish coloured metallic rock of Oviak is stated by the author to be as follows:—Metallic iron in free state, 40.94; iron combined with oxygen, sulphur, and phosphorus, 30.15; combined carbon, 3.0; free carbon, 1.64; nickel, 2.65; cobalt, 0.91; sulphur in the state of sulphuret, 2.70; arsenic, 0.41; phosphorus, 0.21; silicon, 0.075; nitrogen, 0.004; oxygen, 12.10; constitutional water, 1.95; hygrometric water, 0.91; sulphate of lime, 1.288; chloride of calcium, 0.039; chloride of iron, 0.027; chromium and copper, 1.01. The author describes at length his method of analysis, and devotes several pages to the discussion of the following points:—Comparison of this rock with meteoric stones and with other rocks met with on our globe; conditions of formation of the Oviak and other carbon-containing meteorites, and their synthetic imitation.

Solution of Carbonate of Lime by Carbonic Acid.—Th. Schlosing.—This memoir contains a lengthy account of a series of experiments made with the view to elucidate the action of carbonic acid present in arable soil, from which the following conclusions are drawn:—When carbonate of lime, in excess, is placed in an atmosphere containing a constant proportion of carbonic acid, water simultaneously dissolves free carbonic acid, neutral carbonate, and bicarbonate of lime. The carbonic acid is dissolved according to the well-known proportions, and as if the water contained no carbonate of lime; the solution of neutral carbonate takes place as if in pure water free from carbonic acid; as regards the solution of bicarbonate of lime, its proportion depends, for a given temperature, on the tension of the carbonic acid gas contained in the gaseous mixture experimented with.

Industrial Preparation of Aniline Colours.—MM. Girard and De Laire.—Reserved for full translation.

Newly-contrived Galvanic Element, more particularly Arranged for Therapeutic Purposes, and to be Used with Sulphate of Copper.—J. Morin.—The description of an apparatus which is an improved modification of Daniel's galvanic element, yielding a very regular and continuous current.

Some Paraffin Compounds.—P. Champion.—By the prolonged action, aided by heat, of nitrosulphuric acid upon paraffin (the variety prepared from boghead mineral fusing at 53°), the author has obtained paraffinic acid, a fluid which does not solidify at -10°; sp. gr. at 15°=1.14; it is insoluble in water, but soluble in ether, alcohol, wood-spirit, and amyl alcohol; its reaction is acid; it burns with a luminous flame; it is soluble in and forms compounds with ammonia,

soda, and potassa; formula, $C_{22}H_{46}NO_{10}$. Its composition in 100 parts is—Carbon, 56.53; hydrogen, 9.42; nitrogen, 5.07; oxygen, 28.98. The soda salt of this acid is soluble in water, but the baryta and silver salts are insoluble in that fluid. The ethylic salt of the paraffinic acid is a solid body, soluble in alcohol and ether; formula, $C_{22}H_{42}(C_2H_5)NO_{10}$. The properties of the methylic and amyllic salts of this acid agree with the ethylic salt. By causing nitrosulphuric acid to act for ten days upon paraffin, a compound, $C_{22}H_{42}NO_{12}$, is obtained. Paraffin is readily and rapidly acted upon by fuming nitric acid at 110° under pressure. The action of chlorine, bromine, and iodine upon paraffin is briefly alluded to; the two first-named haloids appear to form compounds with paraffin, but, even at 200°, iodine scarcely acts upon paraffin.

Among the large number of memoirs and papers contained in this number, and bearing upon natural history and other sciences, we call attention to the following essay:—

Dr. Liebreich's Experiments made to Prove that Strychnia is the Antidote of Chloral.—M. Oré.

Gazzetta Chimica Italiana, No. 4, 1872.

The following is the only original paper contained in this number:—

On Chloropicrin.—A. Cossa.—The author first describes, at great length, the rather complicated method of preparation of the body alluded to, which boils at 112.8°, distils without decomposition, but detonates when rapidly heated above its boiling-point. Chloropicrin is readily soluble in benzene, sulphide of carbon, ethylic and amyllic alcohols, but is not very soluble in ether; chloropicrin dissolves iodine, caoutchouc, resins, cinnamic and benzoic acids. The author gives, further, an account of his researches made for the purpose of converting chloroform directly into chloropicrin, but this did not succeed; we also find a detailed description of the action of chloropicrin upon alcoholic sulphhydrate of ammonium, whereby a violent reaction takes place, and there is formed carbonic acid, sulphuretted hydrogen, sulphur, and also an organic compound smelling like garlic.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 12, 1872.

This number contains the following original papers and memoirs:—

Red Colour sometimes observed in White-Lead.—A. Bannow and G. Krämer.—This memoir contains an exhaustive account of a series of experiments made with eight samples of lead obtained from English, Belgian, and German lead-works, each sample weighing about 50 kilos. It should be observed that the red colour sometimes met with in white-lead is considered to be due to the presence of silver in the lead. The authors, abstaining from any *a priori* opinion on this question, have tried to solve it experimentally, and have therefore made accurate analyses of the samples, with the special view to estimate the impurities (foreign metals) in lead, and for the estimation of sulphur in metallic lead. The authors have devised an ingenious method, which consists in the conversion of the lead, while molten, into chloride of lead, the sulphur being converted into chloride of sulphur, which, being decomposed by water, is converted into sulphuric acid. In addition to tabulated forms containing the results of analysis, this lengthy memoir contains the account of another series of experiments, made with different samples of lead converted into white-lead by processes industrially used. It appears that, provided the quantity of silver present in lead is, as is usually the case in soft lead, very small, the reddish tinge occasionally observed in white-lead is due, not to the presence of silver, but to a defective process of manufacture. This extensive memoir is a valuable contribution to the practical knowledge of white-lead manufacture, and also to the metallurgy of lead.

Joint Action of Heat and Pressure upon Paraffin.—T. E. Thorpe and J. Young.—After briefly referring to a memoir on this subject read at a meeting of the Royal Society, the authors state that they have made experiments on the joint effect of pressure and heat upon paraffin on the larger scale. 3½ kilos. of paraffin (fusing at 46°, sp. gr. at 13°=0.906) yielded about 4 litres of fluid hydrocarbons, of which 0.3 litre boiled below 100°, 1.0 litre at from 100° to 200°, and 2.7 litres at from 200° to 300°; there remained a solid residue in the retort, which, on being treated with ether, was found to have a constant melting-point 47.5, and to consist, in 100 parts, of—C, 85.19; H, 15.34. By the action of bromine, this body was found to belong to the C_nH_{2n+2} series. The authors next describe the results of the fractional distillation of these fluid hydrocarbons. After treating the liquids thus obtained with bromine, these substances were found to be—Pentane, boiling-point 35° to 37°; hexane, 67° to 68°, sp. gr. at 18°=0.6631; heptane, 97° to 99°, sp. gr. at 18°=0.6913; octane, 122° to 125°, sp. gr. at 15°=0.7165; nonane, 147° to 148°, sp. gr. at 13°=0.7279. These hydrocarbons are stated to belong to the series—

Acrylic Acid Ether and Acrylic Acid.—W. Caspary and B. Tollens.—By withdrawing the bromine (*entbromung*) from bibromopropionic acid in alcoholic solution, by means of zinc and sulphuric acid, the authors have prepared acrylic acid ether, $C_3H_5O_2.C_2H_5$, a colourless fluid which has a corrosive action on the skin and a very penetrating smell. The formation of this body from bibromopropionic acid is elucidated by the following formula:—

Free acrylic acid at the ordinary temperature is a liquid, but at -15° it becomes a solid crystalline substance. The authors intend to continue their researches.

Conveniently Arranged Gas-Evolving Apparatus.—V. Wartha.—The description, illustrated by woodcuts, of apparatus intended for laboratory use.

An Observation.—W. Markownikoff.—The contents of this short notice relate to the rectification of an error made in one of the papers read by the author at a meeting of the Russian Chemical Society, and misreported in its proceedings.

Reduction-Products of Silicic Acid Ether.—A. Ladenburg.—After briefly referring to his former researches on this subject, the author gives an account of silico-heptyl-hydrogen, $\text{Si}(\text{C}_7\text{H}_{15})_2\text{H}$, a liquid substance boiling at 107° , smelling like benzoline, insoluble in water and in sulphuric acid, soluble in alcohol and ether, sp. gr. at $0^\circ = 0.7510$, vapour density = 1.875. This substance is violently acted upon by bromine, the result being the formation of silico-heptyl-bromide, $\text{Si}(\text{C}_7\text{H}_{15})_2\text{Br}$, a fluid which emits dense fumes by exposure to air; it is yellowish coloured, and gradually decomposed by contact with water. Silico-heptyl-hydrogen is strongly acted upon by strong nitric and fuming sulphuric acids. These reactions give rise to the formation of various new compounds.

Nature of the Silicium Compounds met with in Plants.—A. Ladenburg.—Since the brilliant results of the author's researches have proved that there exists a chemical connection between carbon and silicium, the author discusses in this paper the functions of silicium in plants, and supports his views by reporting the results of experiments which seem to show the existence in plants of organic silicium combinations.

On Propargyl-Alcohol.—L. Henry.—Propargyl-alcohol, C_3H_3 —HO, is formed by the action of caustic potassa upon monobromated allylic alcohol. The propargyl-alcohol is a colourless, mobile, agreeably-smelling fluid; sp. gr. at $21^\circ = 0.9628$; boils at from 110° to 115° ; vapour density (calculated), 1.93. This alcohol burns in the air with a highly luminous, but sooty flame; its constitutional formula is $\text{CH} \equiv \text{C} \text{---} \text{CH}_2(\text{HO})$.

On Sappanin.—J. Schreder.—This substance has been discovered by the author in the commercial extract of sapan wood (*Casalpinia sappan*) by treating it with caustic soda. Sappanin is a solid, crystalline, white-coloured body, soluble in alcohol, ether, and boiling-water, and insoluble in chloroform, sulphide of carbon, and benzol. The aqueous solution imparts to chloride of iron a cherry-red colour, while with alkaline hypochlorites a grass-green colour is obtained. Sappanin reduces nitrate of silver, and also the Fehling's copper solution. Air-dry sappanin loses, at 100° , 14.17 per cent of water; the empirical formula of this neutral substance is $\text{C}_{19}\text{H}_{19}\text{O}_4 + 2\text{H}_2\text{O}$.

Observations on Landolt's Method of Determination of the Molecular Weight of Bodies from the Volume of Vapour, and Proposed Modification of Grabowski's Apparatus for the Estimation of the Vapour Density.—L. Pfaunder.—Notwithstanding the scientific value of this memoir, its contents are not well suited for abstraction.

Origin of Urea in the Animal Body.—O. Schultzen.—This memoir contains the detailed account of some researches and experiments made with living animals for the purpose of elucidating the origin of urea in the animal body. The urine of dogs fed with methyl-glycol or with sarkosine was found to contain compound ureas, corresponding in quantity with the doses administered of the above-named substances.

Bulletin de la Société Chimique de Paris, Vol. xvii., No. 9, May 1, 1872.

From the *procès-verbaux* of the last meeting of this society, published in this number, we abstract the following particulars:—

Platinic Derivatives of the Trichloride of Phosphorus.—Dr. Schützenberger and M. Fontaine.—The compound $\text{P}(\text{C}_2\text{H}_5\text{O})_3\text{PtCl}_3$ is decomposed by heat, yielding hydrochloric acid, ethylen, chlorated ethylen, and hydride of methyl; the residue contains phosphoric acid and a metallic-looking substance, which appears to contain PCPt. When the above-named compound is dissolved in ammonia, it yields, by evaporation in vacuum, a deliquescent crystalline mass—

The compound $\text{P}_2(\text{C}_2\text{H}_5\text{O})_6\text{PtCl}_3$ also yields—

Tetrachloride of Naphthalene.—M. Grimaux.—The compound alluded to, $\text{C}_{10}\text{H}_6\text{Cl}_4$, yields, on being heated up to 200° along with water, a body which is soluble in boiling water, crystallisable, fusible at 142° ; formula, $\text{C}_{10}\text{H}_{10}\text{Cl}_2\text{O}_2$.

The following original papers and memoirs are contained in this number:—

Borate of Lime from Peru (District of Tarapaca).—Dr. Thiercelin.—This memoir treats on the locality where this mineral is found, its origin, and its composition. It appears that the mineral occurs in and near an ancient river bed, while the boracic acid is evidently due to volcanic action. Assuming the mineral to be pure, its composition would be— BoO_3 , 41.78; CaO , 16.47; HO , 42.35; but the real composition of the native mineral as found varies greatly, containing as impurities—Insoluble siliceous matter, oxide of iron and alumina, NaCl , SO_3 , and NaO . The mineral is evidently a borate; its formula is $2\text{BoO}_3 \cdot \text{CaO} \cdot 3\text{HO}$. The quantity of BoO found by the author varied from 16.42 to 23.40 per cent. Dilute hydrochloric acid only dissolves the borate, and this property is applied for the purpose of analysis by the author, who treats the finely-pulverised mineral with very dilute HCl (1 to 50 of water).

On Camphic Acid.—Dr. Berthelot.—The author sets forth in this memoir his reasons for not accepting Dr. Kachler's opinion that camphic acid does not exist. It appears that this acid—resulting, according to this author, from the action of alcoholic potassa upon ordinary camphor—has given rise to much controversy and diversity of opinion.

Combinations of Dulcite with Hydracids and Derivatives therefrom.—G. Bouchardat.—This lengthy essay is divided into the following sections:—Combinations formed of dulcite and hydracids without elimination of water; chlorhydrate of dulcite; bromhydrate and iodhydrate of dulcite; combinations of dulcite and hydracids with elimination of water (ethers of dulcite); monochlorhydric dulcitan; dibromhydric dulcite; bromhydric dulcitan; tetrabromhydric dulcitan. This essay is elucidated with a large number of complex formulæ.

Combination of Binixide of Chromium and Potassic Dichromate; Kalichromic Dichromate.—D. Tommasi.—This paper contains more in *extenso* what has already been noticed (see *CHEMICAL NEWS*, vol. xxv., p. 214). The formula of the salt alluded to is $[(\text{CrO}_2)_2(\text{CrO}_2)_2\text{K}_2\text{O}] \text{H}_2\text{O}$, or $[(\text{Cr}_2\text{O}_5(\text{CrO}_2)_2)(\text{CrO}_2)_2\text{K}_2\text{O}]\text{HO}$.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, May 9, 1872.

The Soumah Iron Mines in Algeria.—C. Mène.—This interesting memoir, elucidated by a series of tables exhibiting the results of analysis of iron ores from these mines, proves that Algeria may become an important iron-producing country; the ores herein described are all of good quality, yielding from 47 to 65 per cent of metallic iron, and all containing manganese, while the insoluble matter is very small in quantity. It appears that the ore is readily accessible, and railways connect the mines with the seaboard.

Foucault's Pendulum for Demonstrating the Rotation of the Earth.—M. Deleuil.—The description, illustrated by a woodcut, of a neatly-made physical instrument for the purpose of elucidating in a lecture-room the phenomenon of the earth's rotation, first exhibited in 1855 in the Panthéon (now Eglise St. Geneviève) by the late Foucault.

Les Mondes, July 11, 1872.

Association Française pour l'Avancement des Sciences.—The first meeting of this association will be held on September 5th in the city of Bordeaux.

Conversion of Electricity into Motion.—Dr. Borlinetto.—The description of an experiment, which can be made with a Holtz's electric machine, whereby the electricity is caused to turn the disc of an electric machine after two large-sized Leyden jars have been introduced into the circuit of the electricity.

Limits of Human Knowledge and Science.—P. A. Cap.

Petites Annales de Chimie.—E. J. Maumené.—The fifth instalment of a monograph treating on the theory of chemistry, illustrated by a series of algebraical and chemical formulæ.

NOTES AND QUERIES.

Laboratory Manipulation.—On page 527 of the *Journal of the Chemical Society* for June, a paper appears, amongst the foreign abstracts, upon two points in manipulation. First, an original method of drying wet bottles is described; and secondly, an ingenious device is named for altering the gauge of glass tubing. It is not my purpose to claim precedence of discovery in reference to either of these communications, though the methods have been employed by me from boyhood upwards; but having contrived a number of expedients for aiding laboratory work, of a similar kind, I do not see what harm it can do me to claim credit for them. As a sample I give a method of emptying large bottles of water in half the usual time. Invert the bottle, and give the contents a rotary motion; the water will then issue in the form of a tube of water, the air entering up the centre without impeding the passage of the water. If this is "abstracted" next month I may feel encouraged to give other processes.—BOTTLEWASHER.

TO CORRESPONDENTS.

* Vol. XXV. of the *CHEMICAL NEWS*, containing a copious index, is now ready, price 12s. 4d., by post, 12s., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 2s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxvi. commenced on July 5th, and will be complete in twenty-six numbers. **READING CASES**, price 1s. 6d. each, post free, may also be obtained at the Office.

Black Ash.—Your communication was unaccompanied with your name and address.

Student.—See reply to "Undergraduate," in our Notes and Queries column, No. 651, vol. xxv., p. 239.

THE CHEMICAL NEWS.

VOL. XXV. No. 661.

ON THE PHYSICAL NATURE OF THE COAGULATION OF THE BLOOD.*

By ALFRED HUTCHISON SMEE, F.C.S.

AFTER passing in review the principal opinions hitherto entertained on the real nature of the coagulation of the blood, the author states that he is led to refer the solidification of fibrin in the process of coagulation to the same class of phenomena as the peñisation of colloid liquids, as already hinted by the late Professor Graham and others. He points out, at considerable length, the chief circumstances which influence the change in colloidal fluids, and proceeds to compare the properties of colloid silica with an organic body of the nature of fibrin.

ON AN IMPROVED MODE OF ESTIMATING MANGANESE.

By HUGO TAMM.

THE title of this note scarcely reads like fact. Whoever would have thought that room for improvement was left in the estimation of manganese, a metal upon which so much has been written, and for the estimation of which so many ingenious and simple processes have been devised? Yet I hope to have no difficulty in showing that the process which I am going to describe is, on account of its simplicity and accuracy, the true mode of estimating manganese; and I have no doubt that it will be universally adopted for that purpose as soon as it is widely known among analytical chemists.

After manganese has been separated from the substances which usually accompany it, this metal exists in the liquor as chloride of manganese mixed with a strong proportion of ammoniacal salts; and chemists were in the habit of separating manganese from this liquor by means of sulphide of ammonium. The sulphide of manganese obtained, after being washed, dried, and calcined, was re-dissolved in acids, and the solution thus obtained precipitated by carbonate of soda. The precipitated carbonate of manganese, after long boiling, was filtered and washed, dried and calcined, and manganese estimated as the oxide, Mn_2O_3 .

This process I need not say was both long and tedious, and attended with real practical difficulties. It was, for instance, difficult to wash thoroughly the carbonate of manganese and free it from carbonate of soda, and generally a complete washing of this precipitate was accompanied by a loss of carbonate of manganese, which, in spite of care and experience in handling it, would pass through the filters.

By the process which I now propose, volatile reagents alone are used, and this, of course, is a most important point; the precipitation is effected in a neutral or slightly acidulated liquor, another important fact; and manganese is precipitated from the liquor in which it exists, after its separation from the substances with which it was originally mixed, in such a condition that the estimation can take place at once, thus saving a deal of time, trouble, and risks.

Consequently we may assume, *a priori*, that this process is very perfect in every respect, and experience will fully confirm this assertion.

Estimation of Manganese.

After manganese has been separated from the substances which may accompany it, it is always possible, by means of hydrochloric acid and ammonia, to transform it into a mixture of chloride of manganese and chloride of ammonium; and by a judicious use of these two reagents, and of the test-paper, it is very easy to obtain a neutral or slightly acidulated liquor. In the course of analysis or assaying, this is the condition in which manganese is generally obtained, and it is upon this liquor that the chemist must eventually operate to recover manganese. From the neutral or slightly acidulated mixture of chlorides of manganese and ammonium, manganese can be thoroughly precipitated, in the state of carbonate of manganese, by means of a slight excess of carbonate of ammonia.

In these conditions manganese is not precipitated, as might logically be inferred, as a double carbonate of manganese and ammonia, but as the ordinary proto-carbonate of manganese or manganous carbonate, and the precipitation thus effected is so perfect, that in the filtrate it is quite impossible to discover a trace of manganese by means of sulphide of ammonium. Indeed, the precipitation of manganese by carbonate of ammonia, effected in the conditions prescribed, is safer than by means of sulphide of ammonium. I do not mean, of course, the colourless recently-prepared sulphide of ammonium, or the one obtained by saturating the liquor with sulphuretted hydrogen and neutralising by ammonia, for this is a trustworthy reagent, but the yellow sulphide long kept in bottles and which one might be tempted to use.

I have ascertained beyond doubt that in this sulphide, and especially in presence of an excess of chloride of ammonium, both sulphides of manganese and zinc are soluble to an unexpected degree. This solubility may be due to the excess of sulphur usually present in the long-prepared sulphide of ammonium; but I suspect also the presence of an ammoniacal salt of the thionic series. I have not investigated further this reaction, and I must be satisfied for the present, with pointing out the little known but important fact mentioned.

The reaction upon which is based the estimation of manganese is rather startling and unexpected, but the estimation of manganese by this process is quite perfect, and cannot possibly be improved, at least so far as accuracy is concerned. The precipitated carbonate of manganese is allowed to settle in a warm place (boiling not being required) and the whole is filtered. The carbonate of manganese thus obtained is a little denser than the one precipitated by carbonate of soda, and it can be washed with facility with hot water, and if a double filter is used, no trace of the precipitate passes through the filters. After drying, the precipitate is calcined, and manganese is estimated as usual in the state of the oxide Mn_2O_3 .

Such is in all its simplicity the improved mode of estimating manganese which I recommend to the attention of analysts. I will now discuss its merits, and expose some of its applications to separation and to analysis.

Separation of Manganese from Lime, Zinc, Nickel, and Cobalt.

After separating manganese from certain groups of substances easy of separation, manganese may still be mixed with lime, zinc, nickel, and cobalt; and the separation of these substances is rather troublesome, but some of them are simplified by the use of the carbonate of ammonia process.

When manganese is precipitated by carbonate of ammonia from the slightly acidulated mixture of chlorides of manganese and ammonium, if lime is present, this earth is precipitated with manganese, and consequently this process is worthless for the separation of those two substances.

When cobalt is present, part of this metal is precipitated in the state of carbonate along with the carbonate of

* Abstract of a Paper read before the Royal Society.

manganese, to which it imparts a nice pink colour, and part of it remains in solution. Consequently the separation of manganese from cobalt cannot be effected by means of the carbonate of ammonia process. But when zinc or nickel, or both metals, are present, the separation of these two metals is effected with great perfection, manganese being precipitated as carbonate, and both zinc and nickel remaining in solution. This reaction is rather important, for it is not unfrequently the case that manganese, nickel, and zinc exist in the same liquor, and their usual modes of separation are rather complicated, and this process simplifies them; but from what I have said it must be inferred that, although this process is quite perfect as a mode of estimating manganese, it is not capable of being applied to any extent to the separation of manganese from other substances.

Application of the Carbonate of Ammonia Process to the Estimation of Manganese in Manganese Ores.

On the whole, the chief use of a mode of estimating manganese is the determination of the quantity of this substance in manganese ores. If the ore is contaminated with carbonate of lime, it is first treated with very weak cold nitric acid, which dissolves this substance without attacking sensibly the oxide of manganese, and after a few washings it is treated as an ore containing no carbonate of lime, as follows:—From 20 to 50 grs. of the ore are dissolved in hydrochloric acid, and the mixture is heated until the chlorine evolved is thoroughly disengaged. The solution thus obtained is diluted with water, and filtered in order to collect the insoluble residue; and after being carefully neutralised by ammonia, with the usual precautions, it is precipitated by means of succinate of ammonia. Both iron and alumina are precipitated. The mixture is filtered, and to the clear liquor a slight excess of carbonate of ammonia is added. Manganese is thus precipitated completely in the state of carbonate of manganese. This precipitate is allowed to settle in a warm place; it is then collected on a filter, washed, dried, and calcined, and manganese is estimated as the oxide, Mn_3O_4 .

Estimation of Manganese in Native Carbonate of Manganese.

Native carbonate of manganese generally contains carbonates of iron and lime. From 20 to 50 grs. of this mineral are dissolved in hydrochloric acid, and when the solution is complete, a little chlorate of potash is added in order to oxidise iron. It is worthy of remark that, whenever iron and manganese exist in a liquor in the state of protoxide, previous to their separation iron ought to be oxidised by means of chlorate of potash. The use of nitric acid, which is often recommended for this purpose, ought to be carefully avoided for the reason that, while the chlorine from chlorate of potash can be driven off quite easily, leaving the whole of the manganese in the state of protoxide, the chlorine evolved by aqua regia remains in the liquor so long as nitric acid is present there, and the consequence is that part of the manganese exists in the state of sesquioxide, which is precipitated with iron.

After the separation of iron by succinate of ammonia, manganese is separated from lime by sulphide of ammonium, and the sulphide of manganese obtained, being re-dissolved in hydrochloric acid, is precipitated by carbonate of ammonia, as has been previously described. But if no lime is present, manganese is precipitated by carbonate of ammonia, immediately after the separation of iron.

It may not be out of place to remark here that in every instance the separation of iron from manganese ought to be effected by means of succinate of ammonia, and that the separation by ammonia which is recommended by some authors ought to be entirely rejected as defective, owing to the rapidity with which ammoniacal protoxide of manganese absorbs oxygen from the air, and is pre-

cipitated as sesquioxide. On the contrary, the complete separation of iron from manganese can always be effected with precision by succinate of ammonia, providing the whole of the manganese exists as protoxide, and this condition can always be obtained with absolute certainty if, previously to the addition of succinate of ammonia, the neutral liquor containing iron and manganese is boiled for a little while.

Estimation of Manganese in Native Carbonate of Iron and in Spiegeleisen.

Native carbonate of iron often contains a small proportion of manganese, and spiegeleisen contains from 8 to 12 per cent of manganese. 100 grs. of the mineral are dissolved in hydrochloric acid, and the solution is oxidised by chlorate of potash. 100 grs. of spiegeleisen are dissolved in hydrochloric, with addition of chlorate of potash, or in aqua regia, but in this case the solution must be evaporated to dryness before operating upon, in order to remove every trace of nitric acid. In both instances iron is separated from manganese by succinate of ammonia, and in the filtrate manganese is precipitated by carbonate of ammonia. If lime is present, manganese must of course be separated from this earth by the usual methods before it can be estimated.

These are the chief instances in which the estimation of manganese is useful.

I will not end this note without remarking that the general method of precipitation from neutral or slightly acidulated ammoniacal liquors is capable of being applied to various analytical uses, and in general with great practical advantages.

INFLUENCE OF CHANGES IN BAROMETRIC PRESSURE ON ANIMAL LIFE.

THIS subject has recently been studied by M. Bert, and he communicates to the Paris Academy, in a series of notes, an account of his researches, of which the following is an outline:—

The experiments were made in the physiological laboratory of the Sorbonne. M. Bert first of all communicates certain facts relative to the death of animals subjected to pressures inferior to mean atmospheric pressure, and the state of the air in which they died.

When the pressure to which a warm-blooded vertebrate is subjected is suddenly reduced to 15 or 18 centimetres of mercury, the animal is seized with convulsions, and soon dies; and this is the case, whether the receiver is quite closed, or a current of air is allowed to pass through it. But if the pressure is gradually reduced, it is possible to keep the animal alive at very low pressures, provided the air about it is being constantly renewed. If the receiver is then closed, the animal dies of asphyxia.

In each case, the capacity of the receiver was inversely proportional to the pressure experimented with. The pressure was gradually lowered to the desired point (as the animal appeared able to bear it), the air being constantly renewed. Then the receiver was closed.

In this way, it was found that birds could not be kept living under 18 centimetres; mammals could bear 12 centimetres; for cold-blooded animals the pressure might be lowered still further.

For the same pressure, the animals which left most oxygen and produced least carbonic acid were kestrels, owls, and grown cats; next followed sparrows, frogs, and kittens; lastly, guinea-pigs.

The quantity of oxygen left in the air after death was greater in proportion as the pressure was less. The opposite was the case with the CO_2 .

The numbers for one example may here be given, showing the differences in the composition of the air after death:—

Sparrows.—Pressure of 76·4 c. : CO₂ 15·4 p.c.; O 3·6
55·0 c. : CO₂ 14·7; O 3·6 26·0 c. : CO₂ 7·8; O 11·2
47·0 c. : CO₂ 14·2; O 5·2 19·7 c. : CO₂ 7·1; O 12·8
37·0 c. : CO₂ 11·5; O 7·4 18·0 c. : CO₂ 2·8; O 18·0
30·0 c. : CO₂ 10·1; O 8·7

Now, in the above cases, the animal's death does not arise from mere diminution of pressure, interfering directly, as a physical agent, with the respiratory movements, or those of circulation; for a sparrow, *e.g.*, may be kept alive at 12 centimetres pressure if oxygen be allowed to enter, whereas it would die at 18 centimetres pressure if the receiver were kept closed. The death is due to the fact that the pressure of the oxygen in the enclosed space is not sufficient to preserve in the blood the quantity of oxygen necessary to the vital functions.

In a second series of experiments, the confined air was raised above the normal pressure. The animals were sparrows, rats, and frogs. It took about fifteen minutes to produce a pressure of seven atmospheres. However quickly the required pressure was reached, the animal did not seem much affected; the breathing became gradually slower till symptoms of asphyxia commenced, and the animal succumbed without convulsions, having a temperature of 22° to 27°, or a little above that of the surrounding air. It is clear that the animal had at its disposal quantities of air, and therefore of oxygen, proportional to the pressure employed; yet, whatever the pressure, death ensued always in very nearly the same time (about three hours for sparrows). And though the pressure was increased by injecting fresh air, the animal was not relieved; it was relieved, on the other hand, when the air was allowed to escape.

After death, the blood in the arteries and in the veins was, in most cases, very red, and bubbles of gas were found in the right cavity of the heart.

As to the composition of the air in which the animals died, here are the results for sparrows:—

	Normal pressure	Carbonic acid.	Oxygen.
1½ atmospheres		16·0	3·5
2		15·2	2·6
2½		13·7	5·0
3½		11·3	8·5
5		7·2	11·1
7		5·6	13·8
9		4·0	15·9
		3·0	17·2

Generally, the greater the pressure, the less did the animal alter the air at its disposal.

It further appears that, for 2 atmospheres and upwards, the value of the pressure of the carbonic acid is always nearly the same. Thus, 13·7 per cent of carbonic acid at 2 atmospheres represents, at normal pressure, $2 \times 13·7 = 27·4$; at 2½ atmospheres, 11·3 per cent represents $2·5 \times 11·3 = 28·25$; in the same way, $3·75 \times 7·2 = 27$; $5 \times 6 = 25$; $7 \times 4 = 28$; $9 \times 3 = 27$.

Death takes place when the carbonic acid contained in the venous blood is unable to escape across the lungs, owing to the pressure of carbonic acid in the atmosphere. And we are led to the conclusion: That a sparrow necessarily dies when there is in its venous blood such a quantity of carbonic acid as equilibrates the pressure of 26 or 28 per cent carbonic acid in the external air. For mammals, the number is slightly higher; for reptiles, it falls to 15 or 16. This explains how the birds died all in the same time, whatever the pressure, and how injected air did not relieve them.

The numbers arrived at by experiment led to the further principle that, as regards normal and lower pressures, a sparrow necessarily dies when the quantity of oxygen contained in its blood equilibrates a pressure of about 3·5 of oxygen contained in the external air.

It appears that the proportion of gases in the blood may occasion the death of an animal in three ways—(1) through insufficiency of oxygen (the pressure of the air being 1 atmosphere or under); (2) excess of carbonic

acid (pressure of 2 atmospheres and upwards); (3) both of these combined (pressures intermediate between 1 and 2 atmospheres).

M. Bert next endeavoured to find whether the law relative to the proportion of carbonic acid held good under two atmospheres, by eliminating the cause of death, which consisted in deficiency of oxygen. He used atmospheres which were richer in oxygen than common air. Down to 25 centimetres pressure the law was verified; *i.e.*, the number expressing the quantity of carbonic acid, multiplied by the number expressing the pressure gave 25, or nearly so. Below 25 centimetres there was divergence.

The explanation given is, that at these low pressures the proportion of oxygen, considered in relation to the normal pressure, is a very small one, and that even in these superoxygenated atmospheres the animal dies of want of oxygen.

On the above principles, it ought to be possible to keep a sparrow alive in an atmosphere of pure oxygen with a pressure little over 2·66 c.

Animals were next confined in superoxygenated air, the pressure of which was over 2½ atmospheres. Here the law above indicated was departed from. But an unforeseen result was met with. When the pressure was raised to 4 or 5 atmospheres, the animal gave signs of suffering and fell into convulsions, which were repeated up to the time of its death (in less than half an hour). These violent effects could not be due simply to pressure, for in common air the animals bore a pressure of 8 or 9 atmospheres without inconvenience. They are due to the larger proportion of oxygen, which, entering the blood, acted poisonously. To produce the same results by simply using air, it would be necessary to exceed 14 atmospheres. Oxygen, therefore, when its proportion in the blood is notably increased, acts as a poison.

At a later period, M. Bert was able to apply a pressure of 20 atmospheres. With common air, the convulsions due to poisoning by oxygen appeared at 15 atmospheres.

Still M. Bert thinks (and he gives proof of it) the injurious action of oxygen must not be supposed only to commence there. It begins to act thus at 6 atmospheres, or (as more refined experiment may yet show) at even lower pressures.

The benefit derived from use of compressed air-baths, on the one hand, and many of the accidents that happen to workers in mines, in diving-bells, &c., on the other, appear to be due, in great part, to the introduction into the system of a quantity of oxygen greater than in the normal state; and it is with oxygen as with other poisons, small doses of which may be salutary.

If aeronauts, who are stopped in their upward course, not by failure in the balloon, but by the impossibility of living, wished to soar higher, they might accomplish this if they took with them a supply of oxygen to which they could have recourse when the air became too rare. The mechanical arrangements for breathing this conveniently can be easily conceived.

On the other hand, the industries which subject workmen to pressures over 5 or 6 atmospheres entail suffering and death; which evils might be remedied if there were substituted for the air a mixture of air and nitrogen, calculated so that the pressure of the oxygen should not exceed a certain low limit. A. B. M.

ON THE EVIL EFFECTS OF THE USE OF ARSENIC IN CERTAIN GREEN COLOURS.*

By FRANK W. DRAPER, M.D.

(Continued from p. 31).

II. Confectionery, Pastry, Ornaments, and Toys.—It would seem hardly possible that any person, save the

* From the "Third Annual Report of the State Board of Health of Massachusetts."

most reckless or the most malicious, would designedly introduce into articles of food agents of such poisonous potency as the green colours containing arsenic. Ignorance of the properties of Schweinfürdt green must have been the only extenuation for the great majority of those confectioners who have ever made use of that substance to impart to their wares a luring but most treacherous colour. Doubtless all the colouring materials which are used so abundantly to give to candy its variegated hues should justly be subjected to the closest scrutiny, and many of them should be unconditionally condemned in view of the baneful effects which they necessarily produce, especially in children. It needs no argument to demonstrate the probable results of the swallowing of even the smallest portion of a colouring material which contains more than one-half its weight of pure arsenic; and a single word of warning ought to suffice to banish such sugar-coated poison from candy-shop windows.

It is a matter for congratulation that, as the result of stringent regulations in other countries, together with a more general enlightenment of the public in such matters, accidents from the use of the metallic pigments in confectionery are now comparatively rare. Repeated and fearful experiences in the past, of which the victims were chiefly children, have borne their fruit. It would probably be a difficult task at the present day to find the arsenical greens designedly incorporated as a colour into any candy intended for eating. It would be better for the community if experience had taught similar abstinence concerning the green pigments in other relations.

Accidents do, however, occasionally occur from the ornaments with which confectioners adorn their pastry, and which are not meant to be eaten. These are not unfrequently coloured in the most reckless manner with emerald green. Misadventures from this source generally affect children who, attracted by the colour and the candy-like aspect of the ornaments, eat them inadvertently. A number of cases of this sort are reported. In one such instance, two children ate a portion of a cake ornament which was coloured green, and narrowly escaped death. Ten grains of the coloured pastry contained nearly 2½ grains of arsenic.* Dr. Fergus reports a similar experience, in which three children were poisoned, exhibiting all the typical symptoms of the effects of arsenic.† In 1857, in Edinburgh, eighteen persons were made very seriously ill; and one child died, after eating a pastry ornament which owed its green colour to arsenite of copper.‡

The ingenuity of caterers has sometimes shown itself in the presentation of the triumphs of their art in a unique manner. M. Chevallier relates, that at a grand dinner-party in Paris, attention was directed to a boar's head which had been curiously decorated for the occasion. The ornament consisted of masses of fat, coloured alternately red and green, so arranged as to give quite an artistic effect. One of the guests, well acquainted with chemistry, was struck with the rich green colour, and reserved a portion for private analysis. He found the colouring matter to be pure Scheele's green, forming about 2 per cent of the weight of the fat. It appeared, on inquiry, that the butcher's boy had procured the colour from an adjacent shop, in spite of the regulation prohibiting its sale.||

The toys of children are a medium by which these poisonous pigments may be introduced into the system and cause grave accidents. Many of the green wooden toys are painted with Schweinfürdt green loosely applied, the colour being mixed with water only and smeared on the wood, instead of being more securely fixed upon the material by means of oil or varnish; and when one remembers the instinctive habit of young children to carry

to their mouths whatever their hands contain, the liability to injury is at once apparent. Moreover, children's hands are always moist, and this moisture can readily dissolve and detach the loosely applied colour. The hands thus soiled are put to the face, and, as likely as not, in the mouth. This custom of using the metallic colours on toys is the more reprehensible since it is wholly unnecessary, or, if any colour is desirable, vegetable pigments should be substituted. Chevallier cites two cases of acute arsenical poisoning in children from the source alluded to, and remarks "It is a matter of surprise that other cases have not been brought to the notice of the public, since children are so often seen playing with those cheap toys, with their hands abundantly daubed with yellow, red, and green."

The boxes of water-colours which are in such common use as a plaything for children, contain generally two blocks of green paint, one being of a dark and the other of a light shade. The latter consists of arsenical green. A tablet of this kind, weighing 38·26 grains, was analysed for the writer by Mr. A. H. Pearson at the laboratory of the Massachusetts Institute of Technology, and found to contain 8·89 grains of arsenic. A child in using these paints will frequently carry the brush to his mouth, in order to moisten it with saliva before applying it to the colour, and sometimes the paint is itself touched directly to the tongue. It is marvellous that more frequent cases of poisoning from this source do not occur, because not only the green colour, but others also of the blocks, are composed of matters of a positively harmful nature. Must it not be considered as hardly less than criminal in the manufacturers of toy paint-boxes to distribute a colour containing so large a proportion of one of the most irritant poisons?

It has happened that children, too young to know the use or nature of these paints, have eaten portions of them, and have been seriously poisoned in consequence. Such an instance was reported in 1859 by Dr. Rose; the child took only a small fragment of a green paint, and in half an hour he became cold, pulseless, and fully collapsed. Only by the vigorous application of the proper antidotes to arsenic was the child's life saved.† Four cases, precisely analogous in character, are recorded by Chevallier.‡

III. The arsenical pigments are sometimes used in the *inside painting of houses*, and in this relation they merit a single word. The dangers to health arising from this source are, of course, comparatively unimportant in America, where taste and fashion prescribe the general use of white-lead for these purposes of house painting. In some parts of Europe, however, the use of mineral green has been deemed a matter of sufficient importance, on account of its extent, to warrant an investigation into the effects which may occur. M. Kirchgässer, of Coblenz, published, in 1867, the results of his researches on this subject, and demonstrates the deleterious effects of habitually staying in rooms on whose walls is a coating of arsenical green. The symptoms in such cases are those of chronic arsenical poisoning, and they are identical with those due to exposure under other circumstances; the most characteristic are excessive debility, intermitting pains, cold extremities, a cachectic aspect, and sometimes the appearance of brown patches on the skin.

Dr. Lorinser also asserts his unqualified opinion that chronic arsenical poisoning may occur in consequence of the occupancy of rooms whose walls are painted green, and which owe their colour to the arsenical pigments. Numerous cases occurring in his own experience are cited to demonstrate his statements.||

The following instance illustrates how accidents may arise through inadvertence from the use of arsenical green paint. The experience is not improbable in our own community where the paint is sometimes used on

shelves and such other limited surfaces. A distinguished English chemist, Professor Taylor, observed, adherent to the under crust of the loaf of bread which had been placed one morning before him for breakfast, certain well-marked patches and streaks of a green colour, having the appearance of green mould. He removed some of the suspicious matter, and, subjecting it to analysis, proved it to be composed of "Scheele's green, containing about 50 per cent of arsenic." There was enough on one of the loaves to have killed an infant. On inquiry, it was ascertained that the baker, from whom the bread had been purchased, had just had his shop newly decorated, and there were eight long shelves (holding some hundreds of loaves) painted a bright grass-green colour, top, front, and sides. A number of the loaves were examined in succession, and it was found that they were all similarly stained. They had been placed while warm on the shelves, and had absorbed a quantity of the freshly-applied poisonous pigment. "The baker expressed his ignorance that there was arsenic in the paint; but the painter, who was summoned, took the matter more coolly and professionally, remarking that it was impossible to get a good green without arsenic, that he had used it for many years, and he had never heard of anyone being killed by it." The author remarks: "It is easy to conceive that an accident of this kind, if undetected, might lead to serious results, and perhaps to very erroneous suspicions."*

A case analogous to the foregoing occurred in Vienna. An entire family were made seriously ill by eating strawberries which had been kept a few hours in a box whose inner surface was painted green. The paint, on analysis, was found to be coloured with arsenite of copper.†

IV. Every person must be familiar with the appearance of the brilliant green paper which is used so extensively for covering paste-board boxes, for show-cards, for tickets, for wrappers, for lamp-shades, and for a great number of similar purposes. This paper owes its bright tint in all these forms to the presence of arsenite of copper. It contains a large amount of the poisonous material in proportion to its weight.

The accidents to which this method of employing arsenic may give rise are, as will readily be seen, chiefly of an acute order, and grow out of the danger, to which children are especially liable, of swallowing the poison in the manner alluded to in connection with toys. The matter has received particular attention in France, and the use of arsenical green paper for the purpose of enveloping articles of food, confectionery, and the like is absolutely prohibited. In his instructions to his subordinate officers, the Prefect of Police of Paris applies the interdiction of these papers to "bags, envelopes, boxes, or labels as used by all dealers in provisions or articles of food whatsoever."‡

Such a sweeping proscription would certainly appear impracticable in our own community, but it serves to illustrate the magnitude of the subject as it is regarded in other countries. Certainly the very general use of the material in question, under a great variety of forms, must be obvious to the most casual observer, and when the eye once becomes accustomed to the characteristic shade, and looks for it, it is surprising to observe to what a multiplicity of uses the paper is applied. It will not be unprofitable, therefore, to utter a word of warning concerning the dangers which are possible, and to cite cases which exemplify them.

Perhaps the most reprehensible use to which the green paper is put is as a wrapper to packages of confectionery, chocolate, and the like, a practice which is becoming too common. On of the most reputable of the confectioners of Boston displays in his windows and on his shelves, with other confectionery of his own manufacture, rolls of lozenges enveloped in the bright green paper; and the same custom is to be repeatedly observed in other stores.

Children, readily allured by the bright tint, obtain this candy, and if they do not swallow a portion of the poison with the sweatmeat, are not generally unready to put the paper wrapper to their mouths, child fashion. A case is recorded by Chevallier in which a child was poisoned in this manner by a piece of green paper. The mother of the child had given him a fragment of chocolate, around the end of which, for the sake of neatness, she had wound a portion of the paper in which it was originally enveloped. In sucking the candy, the child also took into its mouth some of the colouring matter from the paper, and narrowly escaped death in consequence.*

An accident like the following is likely to occur at any time to an organism equally sensitive to the action of poisons, where price-cards covered with arsenical green are so freely used:—

"A lady purchased a quantity of prunes, of which she cooked a portion. Soon after eating some of them she was attacked with vomiting, which continued several hours. Not suspecting the cause of her illness, she took more of the prunes, and suffered a recurrence of the symptoms. Then it was noticed, on careful search for the cause of her trouble, that some of the fruit was stained with green. On returning the prunes to the grocer, he recognised the fact that the colour proceeded from a green price-card which had rested on them; the fruit, being moist, had taken up a portion of the colouring matter from the paste-board. The pigment was found to consist of Scheele's green."†

The instance which follows is also suggestive of a quite common exposure:—

"A watchmaker had a very troublesome and irritable ulceration of the mucous membrane of the mouth. The smarting and annoyance were almost intolerable, and became much increased in the evening, when the lips swelled and became so painful that eating, or even speaking, could scarcely be indulged in. In prosecuting his work, he was in the habit, in the evening, of using a gas-light, before which, to protect his eyes, he had a bright green paper shade. On analysis, the colour of the shade was found to be due to the presence of aceto-arsenite of copper (Schweinfürt green). The heat from the light was believed to have decomposed a portion of the arsenical pigment, producing the characteristic odour and causing the acute symptoms in the workman. Speedy recovery followed the disuse of the shade."‡

In 1861, the following case occurred in Boston, and was reported in one of the local medical societies:—A young child, in playing with a small green concert ticket, put it to his mouth, and detached and swallowed a portion of the pigment. Violent symptoms followed. A duplicate ticket was analysed quantitatively by Dr. C. T. Jackson, and was found to contain in its green coating nearly 2 grains of pure arsenic.||

(To be continued).

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.‡

By Dr. F. CRACE CALVERT, F.R.S.

Alkanet.—The root of the *Achusa tinctoria* contains a beautiful red resinous principle, to which Professor Boileau assigns the formula $C_{35}H_{40}O_8$, which is insoluble in water, but soluble in alcohol, ether, and bisulphuret of carbon. To all these solvents it communicates a fine purple colour, which becomes blue on the addition of an alkali. It is not at the present day employed as a dye-stuff, its chief uses being in pharmacy to colour medicines;

in perfumery, to colour bills and greases; and in domestic life to give a tint to the lime-wash used for the walls of private dwellings.

Safflower.—Although this dye-stuff has lost much of its value since the discovery of the aniline colours, it is still extensively used in Lancashire for the production of peculiar shades of pinks for the eastern markets. It is also used for dyeing red tape, and I know no more striking instance of red-tapeism than the love which is shown for this particular dye by the users of this article. Much cheaper pinks can be produced from aniline, and, notwithstanding that many times the attempt has been made to introduce them, it has in every instance failed, because the exact shade has not been attained.

Safflower is the bloom of a peculiar thistle called *Carthamus tinctorius*, which is cultivated in France, Egypt, Spain, Italy, and India. In France and Spain, the small flowers composing the heads of the thistle are picked off and dried in the shade, whilst in Egypt and India they are squeezed, washed with cold water to remove useless materials, slightly pressed into lumps, and dried in the shade; the latter have about double the value of the former. The safflower so prepared only contains 3 to 6 parts per 1000 of the colour-giving principle.

This principle has received the name of carthamic acid, and has the formula $C_{14}H_{16}O_{14}$. A solution of this acid, when dried on a polished white surface, leaves a varnish, having a beautiful red colour by transmitted light, whilst it assumes the iridescence of cantharides when seen by reflected light. It is insoluble in water and ether, but soluble in alcohol. This solution becomes yellow on the addition of sulphuric, nitric, or hydrochloric acid. It is also turned yellow or orange by weak alkalis, and the colouring matter in this latter solution undergoes rapid alteration if exposed to the atmosphere. It is owing to the fugitive nature of the colour, and its easy modification by acid and ammoniacal vapours, that the delicate pinks produced from safflower have been so successfully replaced by the pink aniline dyes.

To prepare carthamic acid, safflower is introduced into bags and washed, till a yellow colouring matter which it contains is removed. It is then mixed with water, to which is added 15 per cent of the weight of safflower taken of crystallised carbonate of soda. After two hours' maceration, the liquor is run off, and cotton yarn dipped in; then lemon juice or citric acid is added to liberate the carthamic acid, which fixes itself on the yarn. Up to this point, the process is the same as that adopted in dyeing fabrics, but to obtain the acid, it is necessary to treat the washed cotton a second time with carbonate of soda, which dissolves out the carthamic acid, leaving a second yellow colouring-matter fixed on the cloth. The carthamate of soda thus obtained is decomposed by tartaric acid, and the carthamic acid falls as a brilliant red amorphous powder, which, when mixed with a little water, is sold as safflower extract, and when dry and mixed with ground talc, is employed as *rouge* by ladies.

There is a particular extract extensively used in dyeing, the preparation of which is a secret. Its value depends on the fact that the carthamic acid is rendered soluble in water.

Cochineal, Kermes, Lac-dye, and Murexide.—I shall now call your attention to four colours derived from the animal kingdom, namely, cochineal, kermes, lac-dye, and murexide.

The first three are distinct species of a peculiar tribe of insects called *Coccina*. The females, from which alone the colouring-matter is derived, form a mass nearly destitute of limbs, and remain attached to one spot on the plants infested by them. The males, on the contrary, are very minute and really elegant creatures, furnished with a single pair of filmy wings. The real cochineal is called *Coccus cacti*; kermes, *Coccus ilicis*; and lac-dye *Coccus lacca* or *ficus*. They all contain the same colouring principle. Although the dyes derived from some species

of these insects were well-known to the ancients, and were much used in Persia and India, the true cochineal has only been known in Europe since the discovery of America by the Spaniards; and since the year 1830 only has it been propagated in the Canary Islands, the island of Teneriffe, Java, and Algiers. The best qualities are still obtained from the republic of Honduras.

The *Coccus cacti* lives on a species of cactus called the *nopal* or *Opuntia cochinilifera*. This plant is indigenous to Mexico, where it grows in the wild state; and from it large quantities of cochineal are collected. It is also extensively cultivated by the native Indians, who often have plantations containing 60,000 plants. The cochineal obtained from the two sources is of different quality; that from the cultivated plant is much superior, and is called *mestique*; that collected from the wild plant is called *sylvestra*.

I will now explain, in a few words, how cochineal is propagated and prepared for market. In the month of May, in the flat lands, and in November in the mountainous districts, the Indians take the stems of the cactus, which they have preserved from a previous crop, and remove from them the young female insects, which are placed on the growing plants, where they grow and multiply with great rapidity. After a period of about three months, the insects are collected into small tin dishes, so formed as to enclose the bottom part of the plant, and by means of a small brush they are swept from each stem successively into it. They are then destroyed, either by being thrown into hot water and afterwards dried in the sun, or in stoves, which gives the black cochineal, called *zacatilla*, or they are placed in a bag and stoved at once, which leaves upon them that peculiar lustrous appearance which characterises the silver-white cochineal, called *blanco*. Although 1 lb. of cochineal contains 70,000 insects, there are millions of pounds imported into Europe every year.

If one of the dried insects be placed in warm water it swells, and takes a hemispheric form, when its structure can be seen. If it is pressed between the fingers, thousands of little red grains are exuded, which, if placed under the microscope, are seen to be minute cochineal insects.

The colouring-principle was first isolated in an impure state by Pelletier, who considered it to be an azotised compound. MM. Arppe and Warren de la Rue, however, found that it contained no nitrogen, and that it had the formula $C_{14}H_{14}O_8$. As it had distinctly acid properties, they gave it the name of *carminic acid*. M. Schützenberger proved that carmine is composed of carminic acid and an organic azotised base called *tyrosine*.

MM. Arppe and Warren de la Rue obtain crystallised carminic acid by the following process. The cochineal is treated with ether, to remove fatty matters, then boiled in water. An acid acetate of lead is added to the solution thus obtained, which precipitates an insoluble carminate. This, after being washed carefully, is decomposed with sulphuric acid, the carminic acid being liberated. The aqueous solution is evaporated to dryness, and the mass treated with alcohol, which, on evaporation and cooling, yields it as a crystalline mass.

As shown by the above process, carminic acid is insoluble in ether, but soluble in water and alcohol. It is dissolved without decomposition by concentrated sulphuric and hydrochloric acids. Carminic acid yields on fabrics, especially on wool, one of the fastest colours known, light and air having no action on it. Chlorine, however, easily destroys it. An aqueous solution of the acid gives the following characteristic reactions. With caustic alkalis, it gives a beautiful crimson-red colour; with oxymuriate of tin, it gives a red precipitate; and with cream of tartar or oxalate of potash, an orange-red precipitate. Alumina removes the whole of the colouring-matter from an aqueous solution. As cochineal is an expensive dye-stuff, it is subject to much fraud and adulteration. One of the most common frauds is practised at Nismes and

other places where perfumery is largely prepared. The cochineal in those localities is put into water for a short time, by which a part of its colour is extracted; it is then dried, and either sold as black cochineal, or placed in a sack and shaken with talc or sulphate of lead, and sold as white cochineal. This fraud is easily detected by grinding the cochineal, and mixing it with water, when the talc or sulphate of lead falls to the bottom. Good cochineal does not leave above 5 or 6 per cent of ash.

It is often advisable before buying cochineal to determine its tinctorial power. This may be ascertained by two or three methods. In the first, equal weights of the cochineal to be assayed, and of one of known value, are treated with alcohol or a solution of alum. The solutions thus obtained are poured into tubes, and placed in a colorometer. This is an oblong box, which has two apertures at each end and two on the top, in a direct line with the end apertures. The tubes are placed through the openings on the top, and, on looking through the end apertures, any difference in intensity of colour between the two liquids can be observed. If a difference is detected, alcohol or water is added to the stronger liquor until there is perfect uniformity of tint. According to the amount of dilution required is the relative value of the cochineals.

A good process was published by the late Dr. Penny, of Glasgow. It consists in exhausting a grm. of cochineal with 50 grms. of potash solution, and this extract is further diluted with 100 grms. of water. The solution thus obtained is mixed with a graduated solution of ferricyanide of potassium (1 grm. of salt to 200 grms. of water) till its colour changes to a dark brown. A solution of bleaching-powder of known strength can also be used for the same purpose. The best method consists in dyeing equal surfaces of flannel in a bath composed as follows:—

For Scarlet Tints.

	Grms.
Water	1250
Cream of tartar	2
Tin composition	2
Cochineal	1

For Crimson Tints.

	Grms.
Water	1250
Cream of tartar	0.75
Alum	1.50
Cochineal	1

The pieces are then washed and dried, and, by a comparison of the relative intensity of shade, the value of the cochineal is determined.

The chief employment of cochineal is for dyeing wool, but it is also employed in calico printing to produce pinks and reds in steam styles.

It will no doubt be interesting to you to know how to determine whether a pink has been produced from a dyewood, a cochineal, or from madder. All these colours are destroyed by chlorine or bleaching powder. A boiling soap solution destroys the wood pinks, communicates a crimson hue to the cochineal dye, and brightens the madder colour. Dipped in a rather dilute solution of hydrochloric or sulphuric acid, fabrics dyed with cochineal are not affected, while those dyed with madder or woods assume a yellow tint, which becomes purple when placed in milk of lime. These cloths, however, if subsequently soaped, will yield their colour if dyed with wood, but not if dyed with madder.

Ammoniacal Cochineal.—When 1 part of ground cochineal is left in contact with 3 parts of ammonia for several weeks, a chemical action ensues, by which the ammonia loses one equivalent of hydrogen, which unites with an equivalent of oxygen of the carminic acid, giving rise to water and an amide compound, carminamide. Adopting M. Schützenberger's formula for carminic acid, the change may be thus represented:—

This compound is also used for dyeing, but before employing it for this purpose it is necessary to add 4 per cent of alumina, in the state of jelly, to the mixture described above. The mass is then slowly evaporated to the consistence of a thick paste. By this means all excess of ammonia is expelled. This preparation is used for dyeing silk, and to produce violet and mauve colours on woollen goods.

(To be continued.)

TECHNOLOGICAL EXAMINATIONS.

ON Saturday, the 20th inst., Prince Arthur presided at a conference at the Society of Arts on the promotion of technical education among the working classes of this country. The assembly included the Lord Chancellor, Sir John Pakington, M.P., Lord Henry Lennox, M.P., Lord De l'Isle and Dudley, Lord Clarence Paget, Lord Alfred Churchill, Major-General F. Eardley-Wilmott, Admiral Ommanney, Professor Huxley, Dr. Lyon Playfair, M.P., Dr. Frankland, Professor Tennant, Captain Donnelly, Dr. De la Rue, Captain Galton, Professor Hughes, and Professor Goodeve.

The Secretary read the Report of the Council, which stated that if this country was efficiently to maintain its manufacturing supremacy in the markets of the world, the technical education of our artisans must be improved; and the Council were of opinion that technological examinations would be of great use in furtherance of this end. The Council had had before them a proposal by Captain Donnelly, that the Society of Arts should establish examinations in the science and technology of the various arts and manufactures of this country, and they proposed to hold the first technological examination in 1873, when the subjects would be the manufacture of cotton and paper.

HIS ROYAL HIGHNESS concluded a practical and able speech by saying:—The Society of Arts are endeavouring to encourage, among those who are practically employed in various industries, the study of art, and an accurate knowledge of its application in each branch of manufacture. The Society will not, however, attempt to teach the practice of those arts. Their object is rather to lay a sound foundation of all the principles on which those practices may be carried out to the best advantage. The Society wish and desire to give certificates, prizes, and scholarships, to those who show that to practical skill as workmen they have added an accurate knowledge of natural principles in those matters. I am certain the necessity and advantage of combining scientific principles with practice will be seen by all. I only wonder that we are but just beginning to undertake this task. The machinery for these technological examinations already exists, and, in fact, the skeleton of industrial Universities is ready to our hands. What we now require is funds to clothe it with and give it life, and to enable it to carry out its work—that is, to obtain sufficient prizes to encourage and reward the deserving youth of this country. If others would only do what Sir Joseph Whitworth has done by his noble endowment for mechanical engineering, we might soon hope to see our most sanguine expectations realised.

The LORD CHANCELLOR briefly moved the first resolution, which approved of the proposed scheme of technological examinations, and considered it well worthy of general support, with the view of meeting the admitted general deficiency of technical knowledge in this country.

DR. LYON PLAYFAIR, M.P., seconded the resolution, which was carried.

MR. WATNEY, the Master of the Mercer's Company, moved that this meeting trusts the advancement of technological knowledge in the manner proposed may be

viewed by the City Guilds, and other like bodies, as an object well worthy of their support and material assistance. He expressed his belief that the Livery Companies were not, as was generally imagined, opposed to the resuscitation of technical education, and would support any good scheme with that view.

Dr. WARREN DE LA RUE seconded the resolution, remarking that if the City Guilds would only contribute a small portion of their funds towards raising the scientific standard of English workmen, it would prove a good investment for the country.

The resolution was carried unanimously.

Sir J. PAKINGTON, in moving the next resolution, which directed the formation of a committee, consisting of the masters of the city companies, the leading manufacturers and scientific professors, and the members of the Society of Arts, urged that the elementary education of the people having been provided for, there was now no longer any excuse for further delaying the consideration of the important question of systematic technical instruction, and that, unless the matter was vigorously taken up, Germany and France would steal ahead of us, while we were supinely thinking we were guiding the manufactures of the world.

Lord DE L'ISLE AND DUDLEY seconded the resolution, which was carried.

A cordial vote of thanks to Prince Arthur for presiding brought the proceedings to a close.

NOTICES OF BOOKS.

A Handbook of Chemical Technology. By RUDOLF WAGNER, Ph.D., Professor of Chemical Technology at the University of Wurtzburg. Translated and edited from the Eighth German Edition, with extensive additions, by WILLIAM CROOKES, F.R.S., &c. With 336 engravings on wood. London: J. and A. Churchill. 1872.

It cannot be denied that, as regards good handbooks on scientific subjects, we are greatly indebted to the zeal and active industry of the Germans; and as regards works on technology, this is still more prominently the case, for in no other civilised country has there been published a work of greater magnitude or intrinsic value than the celebrated "Technologische Encyclopedie" von Prechtel.

The publication of an English edition of the work before us will, we think, be hailed with pleasure, especially as the subject of technical education is now occupying prominent attention. The translator opens his preface with the following sentence:—"The several editions of Professor R. Wagner's 'Handbuch der Chemischen Technologie' have succeeded each other so rapidly that no apology is needed in offering a translation to the public." In order to give our readers some insight into the scope of this volume, we transcribe from the contents the following particulars:—*Division I.*—Chemical Metallurgy, Alloys, and preparations made and obtained from Metals—Iron; Pig or Crude Iron; Malleable, Bar, or Wrought-Iron; Steel; Iron preparations; Cobalt; Nickel; Copper; Lead; Tin; Bismuth; Zinc; Cadmium; Antimony, preparations in technical use; Arsenic; Quicksilver, or Mercury, and its preparations; Platinum; Silver; Gold; Manganese; Permanganate of Potassa; Magnesium; Electro-Metallurgy. *Division II.*—Crude Materials and Products of Chemical Industry—Carbonate of Potassa; Saltpetre; Nitrate of Potassa; Nitric Acid; Technology of the Explosive Compounds; Gunpowder, and the Chemistry of Fireworks or Pyrotechny; Nitroglycerine; Gun-Cotton; Common Salt; Manufacture of Soda; Native Soda; Soda from Plants, or Soda-Ash; Soda prepared by Chemical Processes; Preparation of Iodine and Bromine; Sulphur; Sulphurous and Hyposulphurous Acid; Manufacture of Sulphuric Acid; Sulphide of Carbon; Hydro-

chloric Acid and Sulphate of Soda; Bleaching-Powder and Hypochlorites; Alkalimetry; Ammonia and Ammoniacal Salts; Soap Making; Boracic Acid and Borax; Production of Alum, Sulphates of Alumina, and Aluminates; Ultramarine. *Division III.*—Technology of Glass, Ceramic Ware, Gypsum, Lime and Mortar—Glass Manufacture; Ceramic or Earthenware Manufacture: (1) Hard Porcelain, (2) Tender Porcelain, (3) Stoneware, (4) Fayence Ware, (5) Common Pottery, (6) Brick and Tile Making; Lime and Lime Burning; Mortar: (A) Common or Air-Setting Mortar, (B) Hydraulic Mortar; Gypsum and its preparation. *Division IV.*—Vegetable Fibres and their Technical Application—The Technology of Vegetable Fibre; Flax; Hemp; Cotton; Paper Making: (A) Hand Paper, (B) Machine Paper, (C) Pasteboard and other Paper; Starch; Sugar Manufacture; Cane Sugar; Beet-Root Sugar; Grape Sugar; Fermentation; Wine Making; Beer Brewing; Distillation of Spirits: (A) Preparation of a Vinous Mash, (B) Distillation of the Vinous Mash; Bread Baking; The Manufacture of Vinegar: (A) Preparation of Vinegar from Alcoholic Fluids, (B) Preparation of Vinegar from Wood Vinegar; The Preservation of Wood; Tobacco; Technology of the Essential Oils, Resins, and Caoutchouc Substances; Cements, Lutes, and Putty. *Division V.*—Animal Substances and their Industrial Application—Woollen Industry; Silk; Tanning: (1) Red or Bark Tanning, (2) Tawing, (3) Samian or Oil-Tawing Process; Glue Boiling; Manufacture of Phosphorus; Requisites for Producing Fire; Animal Charcoal; Milk; Meat. *Division VI.*—Dyeing and Calico-Printing—On Dyeing and Printing in General: (1) Aniline Colours, (2) Carbolic Acid Colours, (3) Naphthaline Pigments, (4) Anthracene Pigments, (5) Pigments from Cinchonine; Red Pigments occurring in Plants and Animals; Blue Dye Materials; Yellow Dyes; Bleaching; Dyeing of Spun Yarn and Woven Textile Fabrics; The Printing of Woven Fabrics. *Division VII.*—The Materials and Apparatus for Producing Artificial Light—Artificial Illumination in General: (1) Artificial Light from Candles, (2) Illumination by means of Lamps, (3) Gas, Paraffin, and Solar or Petroleum Oils. *Division VIII.*—Fuel and Heating Apparatus—Fuel in General; Wood; Peat; Carbonised Peat; Brown-Coal; Pit Coal, or Coal; Petroleum as Fuel; Coke; Artificial Fuel; Gaseous Fuel; Heating Apparatus; Heating Dwelling-Houses; Steam-Boiler Heating and Consumption of Smoke.

This is a mere outline of the subject-matter treated of in this work. It should be borne in mind that the book, to which valuable additions have been made, is intended to be a class-book and a guide to both students and teachers of technology; but manufacturers, merchants, and scientific and practical chemists, will meet with valuable information, while for more extensive details the larger work of Dr. Wagner, which consists of five volumes in the German language, may be consulted. We sincerely hope that the study of technology may soon become in this country, as it already is in Germany, an important branch of education in our universities and colleges.

Second Annual Report of the Deputy Master of the Mint. 1871. Presented to both Houses of Parliament by command of Her Majesty. London: Eyre and Spottiswoode. 1872.

At the close of the year 1870, the Assay Department of the Mint underwent reorganisation, the new arrangements involving the abolition of the offices of non-resident assayers, and a return to the ancient system under which all bars when alloyed and ready for coinage are assayed within the Mint itself. To render possible the exercise of a more direct and efficient control over many details upon which the accuracy of coining in a great measure depends, a second Assay Office has been established, and materially contributes to a more rapid execution of the coinage. The advantages of the change are abundantly

shown in the memorandum of Mr. W. Chandler Roberts, the Assayer, annexed to the report of the Deputy Master.

The last year presented some severe attacks upon the resources of the various departments of the Mint, for whereas the yearly average of the coinage of gold is £5,000,000, the demand for gold coin rose to the extraordinary amount of £9,798,735 for British coins alone. This enormous increase has been met with more than average success under the disadvantage of new arrangements, while several points have been gained of material value in the improvement of the gold coinage. For instance, "in the process of annealing additional experience has been acquired as to the manner in which all discolouration of the blanks by the oxidising action of the air may best be avoided, and the result has been an increased brilliancy on the surface of the coins, which contrasts not unfavourably with the hue of pieces to which the operation of blanching has been applied."

The operations of "minting" are far from being of an entirely mechanical nature, for the mechanical processes must be considered as subsidiary to the formation of an alloy of base and precious metals in definite proportions. Moreover the composition of the alloy after melting must be ascertained with the utmost accuracy, and again when the alloy has been converted into coin. Mr. Chandler Roberts has in consequence of these requirements introduced into the New Office the volumetrical method of assaying silver, and the result under his careful management, has in every detail been satisfactory. Mr. Roberts also has found that modern improvements in the process of refining having rendered it possible to extract with profit all the gold in excess of 2 grains in the lb. troy, made experiments to ascertain whether the gold was present in sufficient quantity to render desirable its extraction from the old silver coin now in course of withdrawal from circulation. The results have shown that half-crowns issued during the period between the years 1760 and 1837, contain 4.07 grains of gold in the lb. troy. Accordingly arrangements have been entered into with Messrs. Johnson and Matthey to effect the extraction.

Mr. Roberts's researches on the best method of treating "brittle" gold are very valuable, and we quote the memorandum *in extenso*. "In my preliminary reports upon the method of toughening brittle gold, dated November 19, 1869, and April 20, 1870, respectively, I detailed the experiments which enabled me to recommend that chlorine gas should be employed for rendering ductile gold of which the intractable character had escaped detection when the ingots were imported into the Mint.

"The amount of gold set aside as unfit for working during the coinage of £6,500,000, which was completed in July, 1871, amounted to 40,000 ozs., and I now proceed to describe the method by which this gold was treated; but as the details are necessarily technical, it may be well to repeat that brittleness in gold is usually due to the presence of minute traces of foreign metals, and that these metallic impurities are eliminated as chlorides by the passage of chlorine gas through the molten metal.

"In the melting of gold, as ordinarily practised in the Mint, crucibles of graphite are employed, but such crucibles are not well adapted for use in the treatment of gold by chlorine gas, as the gases evolved from them exercise a reducing action upon the chlorides. It is therefore advisable to substitute crucibles of fire-clay for those of graphite, but, as the workmen of the Mint are unaccustomed to the manipulation of fire-clay crucibles, I was obliged to avail myself of the crucibles ordinarily in use, with the slight inconvenience entailed by the necessity of prolonging by some minutes the time during which the gold is exposed to the action of the chlorine.

"About 1100 ozs. of gold were melted in each crucible, and the chlorine gas was passed through each in succession, the time during which the metal was exposed to the gas varying from 5 to 7 minutes. The gold was found to be perfectly tough, and was re-assayed and again melted with the amount of copper required to form standard gold.

"I append a statement indicating the result of the operations upon 40,000 ozs. of standard gold.

	Ozs.	Ozs.
Amount of initial loss		40'360
Amount of gold recovered from ground up crucibles, borax, &c. }	15'507	
Amount of copper and base metal proved by assay to have been eliminated as chloride. }	24'746	
		40'253
Loss	0'107	

It will be seen that the loss of gold on toughening 40,000 ozs. was only 1-10th of an ounce, and I submit that the experience gained by operating upon an extended scale has fully justified the opinion which I formed from preliminary experiments, and that the process may now be considered to have fairly taken its place as an operation of minting."

The result of these carefully conducted processes is that when during the last trial the jury selected coins, assaying portions of metal from every part of the coin, their verdict was in the highest degree satisfactory, notwithstanding the increased stringency of the examination.

It is interesting as indicating the accuracy attained in the preparation of the gold-copper alloy, that analysis of the assay reports on 1,000,000 of gold coin issued in the ordinary course between the 2nd and 18th of November, 1871, shows that:—

	Per mille of Gold.

6.66 " " "	916.4
16.66 " " "	916.5
15.33 " " "	916.6
27.33 " {were of the exact standard. }	916.666
13.33 " " "	916.7
9.33 " " "	916.8
2.66 " " "	916.9
1.35 " " "	917.0

99.99

Mean composition of the coins { 916.61 gold.
83.39 copper.

1000.00

The limits of the "remedy" permitted by law being 914.6, and 918.6 parts in 1000.

These results are not only good, they are remarkable; for according to ordinary methods of chemical analysis, the deviation from the standard would only amount to a variation of 0.2 per cent, fully in agreement with the remarks of M. Le Jacobi, who represented the Russian Government at the International Monetary Conference held in Paris in June, 1867, and who said, "the tolerance is not an arbitrary stipulation, but is the limit of errors which belongs to every thought, to every chemical analysis, to every composition of alloy, and, as such, depends on the precision of the balances, and the methods employed in the fabrication of money; it may be determined rigorously by applying the calculus of probabilities."

This observation has been borne in mind by Mr. Roberts throughout the important improvements he has effected in the chemical processes pertaining to minting, the consequence being the attainment of an almost unsurpassable standard of accuracy in the composition of the coinage now in circulation.

It may not be uninteresting to shortly sketch the history of the office with which Mr. Roberts is so ably connected. According to Lowndes, the office of "miles argentarius," or assayer of silver, was established in 1180; and in 1222 the office of King's Assayer, whose report was a guarantee to the Crown and to the public of the fineness of the coin, and who was originally also the Warden of the Mint. During the

period between 1544 and 1571 the operations of minting were performed by contract; and it was not until 1851 that the contract system was entirely abolished, and with it the office of King's Assayer, the verification of the coinage being entrusted to eminent chemists having no office in the Mint. The inconvenience of this arrangement led to the re-establishment of an Assay office for verification, and we think that our readers generally will concur with us in thanking Mr. Roberts for the diligence and care he has bestowed upon this department.

CORRESPONDENCE.

PROPOSED ASSOCIATION OF MANUFACTURING CHEMISTS.

To the Editor of the Chemical News.

SIR,—I, with your other correspondents, was pleased to see "Frank's" suggestion for an Association of Manufacturing Chemists, and your favourable remarks on same. There is no doubt such an association is wanted, and if formed, and well conducted, would be invaluable to manufacturers, and might be the means of saving thousands of pounds spent in useless experimental plant. As the provincial chemical societies, however, are, to a great extent, occupied with technical chemistry (though they do not meet the want), and do not show any remarkable signs of vitality, I am only afraid that another, and independent society, might fall into the same lethargic condition. To avoid this, I would suggest the amalgamation of all, or as many as possible, of the existing societies, such as the Chemical Societies, Association of Gas Managers, Alkali Association, &c. Of course the combination formed therefrom would require to take in a very large field, but it would be all the more likely, in my humble opinion, to flourish. With your correspondent Mr. Wilkins, I hope that the Association, if formed, will take in as members those gentlemen of the engineering profession who give a portion of their time to the study of chemical plant. For my part, and as a manager of chemical works, I think a knowledge of engineering quite as essential as a knowledge of chemistry for all those who superintend chemical works. Besides, this has been hitherto so disregarded that I am sure there might be a very great saving in the cost of all chemical plant. And why should we not be able, after a time, if the Association lived and flourished, to start some form of college devoted to the study of the principal things required in the conducting of chemical works?

In conclusion, I will only say a word or two in confirmation of what Mr. Hart says about the narrow-minded policy of secrecy amongst manufacturers dying out. Such is clearly the case, and all are willing to give others the benefit of their experiences, if there is a proper and legitimate medium for doing so. As an example, I may refer you to the two most valuable papers read by Mr. Gibbs before the Newcastle Chemical Society, and published in the *Transactions*, which I see you have had sent you. If one united Society can be formed to take in all branches (even to wages questions) of manufacturing chemistry, I feel sure it will be well supported; but establish another half and half affair only, and I fear it will never do much.—I am, &c.,

BLACK ASH.

[Since the publication of "Frank's" letter and our article on this subject, several correspondents have offered their assistance in the formation of the proposed Association, and letters containing many practical suggestions have appeared in our columns. We are informed that steps have been taken at Newcastle-on-Tyne to organise the Society, and we hope shortly to record the success of the preliminaries.—Ed. C. N.]

TESTING BLEACHING POWDER.

To the Editor of the Chemical News.

SIR,—I have found it very convenient, in the determination of chlorine in hypochlorite of lime (bleaching-powder), to use an acid normal solution of ferrous sulphate, and attach to the bottle, by a copper wire, a rod of zinc, which is immersed in the solution before using it, and reduces the ferric sulphate, that has been formed by the action of the air, to its pristine condition. In this way I believe a normal solution might be used for years. Of course it can be used equally well for the titration of any other oxidising agent, like permanganate of potash or bichromate of potash.

Hoping that this simple suggestion may be of use to some of your readers,—I am, &c.,

S. CABOT, Jun.

Merrimack Print Works,
Lowell, Massachusetts.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

American Journal of Pharmacy, July, 1872.

In addition to several important original papers relating more particularly to pharmacy and pharmacognosy, this number contains the following original papers and essays bearing upon chemistry:—

Cotton-Root.—Dr. E. S. Wayne.—This memoir contains the account of researches made with the root of the cotton plant (*Gossypium herbaceum*), which is used medicinally in some portions of the United States as an emmenagogue, parturient, and abortive, and is said to promote uterine contractions with as much efficiency and more safety than ergot (*Secale cornutum*). The author ascertained that it contained no propylamine or such alkaloids as ergotina and ecbolia, but a red-coloured resinous body was found, which is insoluble in alcohol, chloroform, ether, and liquid ammonia, but is soluble in solutions of caustic potassa and soda. This substance, which appears to be due to the rapid oxidation of a body met with in all parts of the plant, is termed by the author gossypic acid. The author incidentally mentions that cotton-seed cake (the mass left after pressing the oil out) contains more or less of this resin, and that if cows are fed upon it abortion is produced.

On Lobelina.—W. D. Richardson.—The alkaloid just named exhibits a light yellowish colour, and has a somewhat aromatic odour. It is specifically lighter than water, in which it is soluble; this solution has an extremely acid taste; it turns turmeric-paper brown, and red litmus-paper blue. The alkaloid neutralises acids, and forms crystallisable salts, which are soluble in water, less so in alcohol, and sparingly in ether; the acetate of lobelina does not crystallise. One of the most interesting properties of this alkaloid is its decomposition by the aid of heat, either in the free state or as it exists in the herb; it is combined with lobelic acid in the herb and seeds. Boiling water is sufficient to deprive it of its characteristic acid taste; on being combined with strong acids, lobelina is not so affected by heat, but on being simply exposed to air it undergoes a change, whereby it is rendered incapable of uniting with acids to form salts. The mode of preparation is described at great length.

Valuable Products Obtained from the Maclura Aurantiaca, Texan.—The author states the extract of the wood of this tree (a native of Northern Texas, locally known as Bois d'Arc and Osage orange, and cultivated for the purpose of forming hedges) yields with water a decoction used as a yellow dye, while the inspissated aqueous decoction is of such a beautiful yellow colour that it might be properly called aurantine. In addition to this colouring matter, the Bois d'Arc contains a large percentage of tannin; experiments made in Texas prove that hides are tanned much quicker with the wood of this tree than with oak-bark. The seeds from the fruit yield a bland limpid oil, which is used for burning in lamps and also for culinary purposes; this oil resembles olive oil in taste, and it maintains its fluidity at a low temperature.

Notes on American Asphaltum.—Dr. J. S. Newberry.—This essay treats, in the first place, on the origin of asphaltites, the opinion of the author being that all asphaltites are more or less perfectly solidified residual products of the spontaneous evaporation of petroleum.

The chief asphalt deposits of North America (including Canada, New Brunswick, and California) are then briefly described. It appears that asphalt is found in large quantities and in different stages of formation, its origin from petroleum being very plainly exhibited in South California, where the accumulations of asphalt on the coast of Santa Barbara, San Luis Obispo, and other localities, have attracted the notice of all travellers visiting that region. When the asphalt drips from the cliffs, and forms a scum on the ocean off the coast, it is evaporated and oxidised, and then thrown upon the beach by the waves. In the neighbourhood of Chicago, Ill., the limestone formation is in some places saturated with a thick petroleum, which, on exposure to air, is converted into asphalt. At the conclusion of his paper the author says that, notwithstanding the large quantity of asphalt met with in the country alluded to, for practical purposes it will be cheaper and more convenient to bring the Trinidad asphalt to America, because the transport and working of the asphalt found there will be too expensive, and the quantity found in the island of Trinidad (a British colonial possession) is inexhaustible.

The Chili-Salt-petre (Nitrate of Soda) Deposits of Peru.—Dr. J. M. Maish.—It appears that, in many localities of Peru, not only strata of nitrate of soda, but also of borax and other salts, are found, while occasionally a more or less thick stratum of guano is met with between the layers of salt. The mother-liquors left after the crude method of refining the nitrate of soda, yield large quantities of iodine.

Hydrofluoric Acid.—A. P. S. Stuart.—In order to overcome the well-known difficulty of removing from the platinum or leaden vessels the hard, compact, rock-like residue left after the mixture of fluor spar and sulphuric acid is heated for the purpose of evolving hydrofluoric acid, the author recommends to mix with the fluor spar an equal weight of gypsum and the proper quantity of sulphuric acid; the residue left, after the expulsion of the hydrofluoric acid, is then found to be of a pasty nature and is readily removed by water.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
May 19, 1872.

Testing and Verification of Alcoholometers and Areometers.—M. Collardeau-Vacher.—The first instalment of a memoir written to point out the necessity of testing the hydrometers in use for estimating the strength of alcoholic and other liquids, especially for excise purposes. There is added to this memoir a tabulated form exhibiting the density of alcohol (and mixtures of alcohol and distilled water) at 15°, and the corresponding alcoholometric degrees of Gay-Lussac's hydrometer.

Oxyhydrogen Blowpipe.—M. Wiesnegg.—The description, illustrated by woodcuts, of apparatus suitable for smelting substances such as platinum, iridium, and other very difficultly fusible minerals.

Tinning with Zinc instead of Tin.—C. Mène.—The author calls attention to a fraud which, in France at least, seems to be on the increase, viz., that of using zinc instead of tin for the purpose of lining copper vessels, which are in general use for cooking purposes in France; zinc being readily acted upon by weak acids, vinegar, &c., yields poisonous compounds. In order to test the tinning, the author recommends the boiling of vinegar in the vessel; if the surface remains bright, genuine tin has been used, but, if the metallic surface becomes tarnished, zinc may be suspected to have been substituted, and further research will be required before using the vessel for cooking purposes.

Annales des Mines, No. 1, 1872.

This number contains the following original paper relating to chemistry:—

Abstract of the Chemical Analysis made at the Departmental Chemical Laboratory at Mezières.—E. Nivoit and E. Letrange.—A brief account of fourteen analyses relating to iron ores, limestones, marls, fire-clay, and a copper ore; all these minerals are chiefly of local interest, excepting a copper ore from Siegen (Province of Nassau, Prussia), the composition of which, in 100 parts, is—Hygroscopic water, 0.10; quartz, 6.60; copper pyrites, 32.32, consisting of—Copper, 11.56; iron, 9.93; sulphur, 10.83; carbonate of iron, 60.61.

Journal de Pharmacie et de Chimie, June, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

Researches on the Preparation of Atropine from Belladonna Leaves (Atropa Belladonna).—J. Lefort.—From the author's researches—chiefly instituted with the view of obtaining a more advantageous method of preparing atropine for pharmaceutical purposes—it appears that the leaves of this plant contain about 4.5 grms. of the alkaloid to the kilo., and the root from 2 to 3 grms. The preparation of the atropine is described at great length, the main features of this operation being the exhaustion of the dry leaves with boiling hot water to which 10 grms. of tartaric acid to the kilo. are added. The filtered fluid is evaporated to the consistency of a soft extract, which is next treated with alcohol; the alcoholic solution is again evaporated to the consistency of an extract, which is next treated with an ethereal solution of caustic potassa, from which solution the atropine is separated by means of dilute sulphuric acid; the sulphate of atropine is lastly decomposed by means of bicarbonate of soda.

Condensed Report on Artificially-Made Butter Prepared by M. Mège-Mouries.—F. Bondet.—This lengthy memoir enters into details of scientific researches made by the first-named author, upon which he has based a method of preparing from milk and fat (oleo-

margarine) a substance resembling and tasting like butter, which remains sweet for five months after having been made. The mode of preparation of this imitation of butter is described at length, and the reporter comes to the conclusion that in a sanitary point of view the preparation may, if properly prepared, be used with advantage instead of genuine butter, but that the artificially-made product should be designated as such, and put into casks or vessels distinctly bearing the name and address of the maker.

Programm der Königlichen Rheinisch-Westphälischen Polytechnischen Schule zu Aachen für den Kursus 1872-3.

We owe to the courtesy of the eminent director of this establishment the opportunity of again calling attention to the Royal Rhenish Westphalian Polytechnic School, founded by the munificence of H.M. the Emperor of Germany at the ancient capital of Lower Lorraine. The programme before us—a volume of 112 large octavo pages, exclusive of two large tabulated forms—is highly valuable. It should be understood that this institution is in reality a polytechnic university, and those who desire to attend the lectures and enter as students (students in distinction from persons who are usually called "Hospitanten," i.e., those who attend lectures without intending to pass examinations or to receive certificates of efficiency) should have received a sound preliminary education. The course of instruction intended to be given at the Polytechnic School at Aachen from October 7th, is described, and a loose sheet is added containing hints for those who desire to attend the instruction of a polytechnicum, as it is properly termed. The lectures and practical instruction embrace no less than sixty-one different subjects, and include not only all matters relating to mathematics, geometry, and physical sciences, pure as well as applied, but also everything required by the civil and mechanical engineer, architect, industrial and technical chemist, metallurgist, mining engineer, &c. The Polytechnic School possesses excellent libraries, laboratories, workshops, museums, and collections of various kinds, and a catalogue is given of donations during the year from different countries and private individuals (123 in number). Among the donations specially alluded to, mention is made of a complete set of Specifications of Patents, presented to this school by the Right Hon. the Commissioners of Patents for Great Britain and Ireland. Space forbids us to enter into more details; we may, however, mention that 347 persons have attended lectures during second term, including 2 ladies and 260 actual students; 215 were Prussians, 41 natives of other States of the German Empire; 11 Dutchmen, 7 Russians, 6 Belgians, 6 Luxemburgers, 3 Hungarians, 2 English, 2 Norwegians, and 1 from Bohemia, France, Poland, Galicia, Italy, and Roumania, respectively.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale,
No. 235, July, 1872.

This number contains no original papers relating to chemistry, but we call attention to the following memoir:—

Metalliferous Mines of France, not including Iron Mines. A. Caillaux.—This essay contains valuable information relating to the history of the art of mining in, as well as to the mineral wealth of, France.

Report on a New Gazogene Apparatus contrived by M. Maligné.—H. Bouilhet.—Illustrated by engravings, this paper contains the description of a greatly-improved gazogene.

Les Mondes, July 18, 1872.

Coal in Chili.—Rev. F. Moigno.—It appears that very rich seams of coal have been discovered in Chili and in localities not far distant from the seaboard.

German Society of Natural Philosophers and Physicians.—The annual meeting of this Association will be held at Leipzig from the 12th to 18th of August next.

Digitaline.—Dr. Roucher.—The author states that the result of his researches is, that the crystallised digitaline prepared by Nativelle, as well as that prepared by Homolle and Quevenne, is not an active and simple principle, but that both are very complex compounds, and that the elementary analysis of these substances is incorrect.

Saline Iodated Water of Salès.—Dr. Pietra-Santa.—This water is a native spring, situated near Alexandria (Piedmont, Italy); it is stated to possess great medicinal virtues, and to contain a large proportion of iodine.

Forests of Alsace and Lorraine.—Rev. F. Moigno.—At the time when Jules Favre was engaged in treating for peace, his attention was called to the fact that the territory alluded to contains 131,500 hectares of forest land belonging to the State, and worth at least 300,000,000 francs, and that the giving up of this estate should be considered in the sum of indemnity to be paid by France. M. Jules Favre appears to have taken no notice of the hint given him. Prussia has therefore obtained this valuable property *par dessus la marche*.

Cenotannin.—M. Maurial.—After an experience of forty years, the author recommends this preparation to wine growers for keeping wines in good and sound condition without imparting to them a bitter taste.

Bibliography.—Under this heading, attention is called to the following pamphlet:—"*Simple Indications pour Propager l'Emploi de l'Engrais-Vidanges dans les Diverses Contrées de France, et Note Relative aux Engrais Vidanges de Paris.*" Par Maxime Pautet. 8vo., 46 pp. Paris: Lacroix, éditeur, 1872.

Phosphoric Acid and Superphosphates Manufactory.—M. Blanchard.—An account is given of the method of preparing the sub-

stances alluded to as made at Puteaux, near Paris. In order to obtain phosphoric acid, the superphosphate (prepared from rich native phosphatic minerals) is mixed with water (2000 kilos. to 1000 kilos. of superphosphate), and this mixture put into stout linen bags and submitted to strong pressure by the aid of hydraulic presses. The liquid is collected in tanks, and next evaporated and concentrated: what remains in the bags is sold as superphosphate at 10 per cent. The lime is eliminated from the phosphoric acid-containing liquor by means of sulphuric acid, sulphate of lime being deposited by the concentration of the phosphoric acid solution.

Le Moniteur Scientifique Queneville, No. 367, July, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Study on the Quantitative Estimation of Phosphoric Acid in all Products of Agricultural Interest and those belonging to the Domain of Physiology.—Dr. Joulie.—The second instalment of a very complete monograph on this subject (see *CHEMICAL NEWS*, vol. xiv. p. 646). We regret that this excellent memoir is too long to be reproduced in full. There is added to this portion a letter from Dr. Bobierre, the celebrated agricultural chemist at Nantes, explaining his views on the memoir.

Analysis of Fossil Phosphates.—Dr. A. Bobierre.—This excellent essay, also too long for either reproduction or abstraction, winds up with the following general conclusions:—The only proper method of analysis of fossil phosphates is that whereby the phosphoric acid is separated. The commercial method of analysing bone-ash, bone-black, and similar products may be advantageously applied in many cases, provided care be taken to use pure ammonia, and also that the ammonia precipitate be not exposed too long a time to the air; this method should only be applied when agreeable to both seller and buyer.

The Eucalyptus Globulus considered from an Industrial, Hygienic, Economic, Medicinal, and Pharmaceutical Point of View.—F. Papillon.—This memoir treats at great length on a tree, native of Van Diemen's Land, or Tasmania, discovered there first on May 6th, 1792, by the French admiral, Labillardière, while in command of the *Entrecasteaux* and in search for *La Perouse*. From this essay, it appears that the cultivation of this tree, already acclimatised in Southern Europe and Algeria, may become of very great importance. The tree will not thrive in countries where the winters are rather cold. The tincture of Eucalyptus is stated to be an excellent remedy against ague and intermittent fever, especially that kind which is often endemic in marshy districts.

Improved Panification Process.—MM. Sauer and Cachal.—The authors have invented a liquid, to which the name "extract of yeast" is given, and which is so manufactured that, according to the different requirements of the baker, he can use a stronger or weaker fluid for the purpose of producing fermentation. The improvement upon the ordinary plan consists in a greater yield (from 16 to 20 per cent more) of bread, while also the production of alcohol and acetic acid (formed from the former) is prevented, and thus the gluten of the flour kept in a more sound state. The liquid alluded to is composed of some ten different ingredients.

Beet-Root Sugar Extraction.—M. Woestyn.—The description of an improved process of treating the beet-root juice, consisting mainly in precipitating, by means of a current of carbonic acid, the lime usually added in the first operation of treatment of the juice. The result is that, along with the precipitate of carbonate of lime, a great many impurities are thrown down.

Theory of the Mordanting with Alum of Woollen Goods.—P. Havrez.—This essay is divided into the following sections:—Active causes during the aluming; effects of dissociation and absorption; the alum-bath; effects of the two dissociated hydrates (viz., of alumina) upon wool:—(a) in a quantity fifteen times larger than the weight of alum, (b) in by far smaller quantity; dilute sulphuric acid and wool; soluble hydrate of alumina and wool; conditions of duration (length of time), quantity, temperature, &c., which cause the increase of the dissociation and absorption of aluming; (a) action of the bulk of water; (b) action of the temperature; (c) action of the quantity of the wool; (d) action of the duration of the aluming. General conclusions:—Large quantities of mordants (salts of alumina, iron, chromium, tin, copper, &c.) act in solution as salts (or even as salts and acids) after having been absorbed by wool. Small doses of these mordants act upon wool as metallic hydrates, the formation of which is aided by prolonged boiling of the materials (viz., wool, water, and alum, or other salts, as the case may be). The unequal absorption by the wool of the dissociated basic hydrates and acids, and the reaction of these bodies, mutually cause these different actions; it thus appears that the excess of salt can be replaced by small quantities of acids or acid salts (of potassium, bisulphate, binoxalate, bitartrate, &c.), which become converted, in the water, into acid and neutral salt. The increase of metallic hydrate fixed is due to the addition of water, the application of heat, and the prolonged keeping of the wool in the bath. The colour which the wool assumes in the dyebeck reacts chiefly upon the first portions of acid hydrate and basic hydrate absorbed by the wool. The acid has a purifying action, and appears also to promote the liberation of the glucose colours (thus forming carmine-red from carmine), while the metallic hydrate fixes upon the wool the variously-coloured lakes.

Bulletin de la Société Chimique de Paris, Vol. xvii., No. 10, May 15, 1872.

This number contains the following original papers and memoirs:—

Action of Water and Heat, or of Heat only, upon Sugar.—E. J. Maumené.—200 grms. of sugar and 1000 grms. of water have

been kept for some twenty-eight hours at the temperature of boiling water; the optical rotatory power of the sugar has then quite disappeared. Sugar and water have been enclosed in sealed tubes and kept for about thirty days at the temperature of boiling water, with the result that the sugar had become entirely converted into an uncrystallisable compound, probably identical with that which Berzelius and Gellé have obtained by rapidly heating sugar to 160°. By heating sugar for eight days consecutively in sealed tubes in steam of 5 atmospheres pressure (75 lbs. to the square inch, and 153° C.), the sugar is converted chiefly into carameline, $C_{12}H_{22}O_{11}$. In conclusion, the author states that sugar, while being refined or extracted on the large scale, should never be submitted to a higher temperature than 75°, because below that degree of heat sugar is not perceptibly altered.

Action of Crystallised Digitaline upon the Combustion (Act of Respiration of the Lungs) and upon Diuresis.—A. Mègevrand and G. Daremberg.—This paper, elucidated by a number of tabulated forms exhibiting the results of experiments, details the observations of the effects of the digitaline alluded to upon the authors, who partook of doses amounting to from one-fifth to one-half milligramme.

Vol. 17, No. 11, June 1, 1872.

Detection of Counterfeited Kirschwasser.—Dr. Bouis.—According to the author, tincture of guaiacum produces, in genuine Kirschwasser (a very strong alcoholic liquor prepared in some parts of Switzerland from a peculiar kind of cherries, which are bruised and crushed along with the stones, then fermented and distilled), a blue colour; but not so in the kirschwasser prepared simply by adding *aqua lauro-cerasi* to spirits. This blue colouration is, according to the author, due to traces of copper, which are found in the genuine spirit, and which gives a blue colour to the tincture in the presence of cyanhydric acid (always present in the genuine kirschwasser).

Memoir on a New Series of Platinic Compounds.—Dr. P. Schützenberger and M. Fontaine.—The first instalment of an extensive monograph, elucidated by a very large number of lengthy and complex formulæ, and divided into the following sections:—Introduction, containing an *expose* of the principal facts studied in this memoir; phospho-platinous chloride, $PhCl_3Pt=PhCl_3PtCl_2$; phospho-platinic chloride, $(Ph_2Cl_2PtCl_2)_2$; phospho-platinous acid, $Ph(HO)_2PtCl_2$.

Oxidation of the Acetons of Phenyl-Acetic Acid.—M. Popoff.—This memoir, elucidated by a series of formulæ, treats on methyl-benzyl aceton and on ethyl-benzyl aceton.

NOTES AND QUERIES.

Amalgams.—During some recent experiments on amalgams, made with dry filings and mercury, with the object of obtaining one free from shrinkage, I find a law which apparently holds good in all cases, viz., that any alloy which when reduced to filings will harden, when mixed with mercury, without shrinkage, is also free from shrinkage when cast. An alloy containing gold, platinum, silver, and tin, if poured at a clear red-heat into a warm iron mould, remains perfectly rigid, and cannot be removed from the mould without considerable force. If this alloy, in filings, is mixed with about 15 to 17 per cent of mercury, and pressed into a solid mass into a mould, it remains tight in its place, without shrinkage, after it has become as hard as good brass, and continued heavy pressure will not force a trace of a coloured solution between the mould and the plug of amalgam. Whether this law holds good with every alloy I cannot say, but it evidently does so with a great many of similar composition to the one mentioned. —THOS. FLETCHER, F.C.S., 15, Bold Street Warrington.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

ON THE LAW OF EXTRAORDINARY REFRACTION IN ICELAND SPAR.*

By G. G. STOKES, M.A., Sec. R.S.

It is now some years since I carried out, in the case of Iceland spar, the method of examination of the law of refraction which I described in my report on Double Refraction, published in the "Report of the British Association for the year 1862."† A prism, approximately right-angled isosceles, was cut in such a direction as to admit of scrutiny, across the two acute angles, in directions comprising respectively inclinations of 90° and 45° to the axis. The directions of the cut faces were referred by reflection to the cleavage planes, and thereby to the axis. The light observed was the bright D of a soda-flame.

The result obtained was, that Huyghens's construction gives the true law of double refraction within the limits of errors of observation. The error, if any, could hardly exceed a unit in the fourth place of decimals of the index, or reciprocal of the wave-velocity, the velocity in air being taken as unity. This result is sufficient *absolutely to disprove* the law resulting from the theory which makes double refraction depend on a difference of inertia in different directions.

I intend to present to the Royal Society a detailed account of the observations, but in the mean time the publication of this preliminary notice of the result obtained may possibly be useful to those engaged in the theory of double refraction.

ELECTROSCOPE PHENOMENON.

PROFESSOR FORSTER, in a recent number of *Poggendorff's Annalen*, gives an account of a curious effect observed in a gold leaf electroscope. He was one day showing to an audience, that if the leaves were in a state of divergence through negative electricity, the divergence would be increased on approach of a *negatively* electrified body, and that it would be diminished in the opposite case.

To prove this, he had a magnified image of the leaves projected on a screen. He rubbed a rod of caoutchouc with catskin, and touched with it the ball of the electroscope. On removing the rod, the leaves showed about 70° divergence. He again rubbed the rod, and brought it from above towards the electroscope, the axis of the former being at right angles to the vertical axis of the latter. Expecting the divergence to increase, he was surprised to find that it diminished, and on further approach became zero; while it increased on slightly removing the rod. If the rod was withdrawn very slowly, the divergence remained zero, but rose again to the former amount as the rod was further withdrawn. Frequent repetition of the experiment gave similar results; only, he remarks, the electrical source must be a pretty powerful one.

After various futile attempts to explain the matter, there arose the doubt whether the divergence which appears after making a rubbed caoutchouc rod touch the ball of the electroscope was really due to negative electricity ($-E$). He became convinced that, while the rod is, of course, negatively electrified, yet the leaves diverge with positive electricity ($+E$).

* A Paper read before the Royal Society.
See p. 272.

He thus describes his experiments:—"Let a caoutchouc rod be rubbed with catskin and brought near the knob of a Fechner electroscope" (in which, it may be explained, there is only one leaf suspended between the opposite poles of a pile). "The leaf then moves to the $+$ pole. The rod is therefore — electrified. Now rub the rod again, and touch with it the knob of the gold leaf electroscope" (with two leaves). "Then remove the rod. Next, let the knob of this charged electroscope be brought near the knob of a Fechner electroscope (uncharged). The leaf of the latter moves to the $-$ pole; the leaves of the former, therefore, diverged with $+E$; and thus the electroscope became + electrified through contact with the — electrified rod.

"It remained to ascertain the reason of this fact, which, once ascertained as a fact, removed the difficulty in the first experiment.

"When the strongly — electrified rod is brought near the knob, there takes place decomposition of the electricity in the electroscope. The $+E$ flows into the knob, in which it is retained by the rod; the $-E$ flows into the leaves, which diverge in consequence. While thus influenced by the rod, $-E$ escapes, and there is a progressive collection and retention of $+E$ in the knob. At the moment of contact between knob and rod, the rod communicates the $-E$, present at its point of contact, to the knob, and this neutralises in the latter a corresponding quantity of $+E$.

As, however, the excited parts of the rod not in immediate contact with the knob do not give up their $-E$, this surplus of $-E$ still carries on the decomposition and retention of electricity in the electroscope; so that there comes to be much more retained $+E$ in the knob than $-E$ in the leaves (for a constant waste of $-E$ takes place in the electroscope). If the rod is now slowly removed, its retentive influence on the knob decreases, and a certain quantity of $+E$ flows into the leaves, neutralising there a certain quantity of $-E$. When the rod is just so far removed that as much $+E$ can flow from the knob into the leaves as there is $-E$ in these, the leaves become un-electrified and the divergence zero. On further withdrawal, still more of the hitherto retained $+E$ flows from the knob to the leaves, and now commences a divergence with $+E$. When the rod is entirely removed, the whole of the hitherto retained $+E$ is free and produces strong divergence. As the rod is approached again, these phenomena are witnessed in reverse order.

"This theory rests on the supposition that the $+E$ which has been separated and retained by the rod preponderates over the $-E$ communicated to the electroscope by contact (which is easily understood, as an electrified non-conductor gives up its electricity only at the point of contact). For this preponderance to take place, it is necessary, as has been said, that the electric source should be a very active one.

"It can, further, be easily shown that in such circumstances the $-E$ flows away from the electroscope (without conduction) if the electrified rod be brought near the knob without touching it. In this case no electricity can flow directly from the rod to the knob, and yet, if after a few seconds the rod be withdrawn, the leaves diverge considerably with $+E$. The explanation is simple.

"The fact, however, that it is possible, by contact of the electroscope with a negatively electrified body, to obtain + divergence, appears to me one of considerable importance.

"Thus, supposing, in the absence of a pile electroscope, it were required to determine whether a body rubbed with a certain kind of material became $+$ or — electrified, it would be a very likely method to first cause divergence in the electroscope leaves with a rubbed caoutchouc rod, and then test the electric state of the body in question by its influence on the divergent leaves, and call it $+$ or — accordingly. On the former supposition, that the leaves diverged with electricity of the same sign as the caoutchouc rod, any such judgment would be absolutely false, A + electrified body would be taken for a —, and *vice versa*.

"Such error might be guarded against if, instead of bringing the caoutchouc rod near the electroscope, a small charge of $-E$ were brought from the former, by means of a proof plane, to the knob of the latter, as the proof plane would not collect sufficient electricity to produce the disturbance observed in the other case."

A. B. M.

ON A NEW SULPHATE OF COPPER VOLTAIC ELEMENT, ARRANGED WITH THE VIEW OF THE APPLICATION OF CONTINUOUS CURRENTS TO THERAPEUTIC PURPOSES.

By M. J. MORIN.

THIS new element has for its object the complete avoidance of the inconvenience which results, in the ordinary sulphate of copper element, from the deposit of zinc either on the copper or the porous cell. It consists of a cylinder of copper, the interior of which is concentric with the cylinder of zinc; the annular space comprised between these two metallic surfaces is divided into two equal parts by a cylinder of filter-paper. Ordinary sandstone is put between the interior surface of the copper and the paper diaphragm, and sublimed sulphur on the side of the zinc; the whole is plunged in a solution of sulphate of copper, which penetrates through the mass by means of the numerous minute orifices freely to the copper.

Some hundred elements prepared in this manner, and frequently in use, have been set up for more than twenty months, and the alteration which they have undergone shows that this is but half the time for which they may be worked; they have been perfectly closed during this time, and have neither been subjected to repair or inspection.—*Comptes Rendus*.

ON THE ESTIMATION OF CITRIC ACID, FREE AND COMBINED, AND ON A NEW SERIES OF COMPOUND CITRATES.

By J. CREUSE, of Brooklyn, N.Y.

HAVING undertaken the study of the citrates as a class, and especially of those of the citrates in which the acid is combined with more than one base, the first difficulty I met was how to determine citric acid without having recourse to the long and complicated process of an organic elementary analysis. I consulted the most recent publications and some eminent chemists without obtaining my desideratum, viz., how to determine citric acid, free and combined, in the same direct manner as sulphuric or muriatic acid. Then the only thing left for me was to try myself and find such a process, in which I succeeded, after many failures, including an explosion of citrate of silver.

As this process may be interesting and useful, I will describe it here.

It is founded on the fact, that, while the alkaline citrates, the alkaline acetates, and the acetate of baryta are freely soluble in alcohol, sp. gr. 0.908 (63° Gay-Lussac), citrate of baryta is completely insoluble in that menstruum, and, when the reagents are neutral, is always precipitated by double decomposition in the shape of the neutral citrate, $3\text{BaO}, \text{C}_{12}\text{H}_5\text{O}_{21}$, with a variable equivalent of water.

As the presence of alkaline or barium acetates does not interfere with the reaction, this enables the chemist

to determine citric acid in almost any shape; for free citric acid may be saturated with an alkali, alkaline citrates may be analysed directly, and other citrates may be decomposed by an excess of caustic potassa, the excess of alkali being neutralised by acetic acid.

This method, presenting some peculiar features, requires to be explained in full.

If the citric acid to be estimated is in the shape of an alkaline citrate, take from 1 to 2 grms. of the salt and dissolve in 10 to 20 c.c. of distilled water; neutralise the solution with acetic acid if it is alkaline, with ammonia if acid; then add a slight excess of a neutral solution of acetate of baryta and twice the volume of the whole liquid of alcohol 95 per cent; allow to rest for from 12 to 24 hours. The citrate of baryta, which was at first in the shape of a thick jelly, will have become, by that time, denser and easier to wash. Transfer the whole to a suitable filter; as some of the citrate of baryta always adheres to the sides of the vessel where the precipitation has been effected, it is recovered thus:—Pour into the vessel 10 to 15 c.c. distilled water, turn it around so as to wet all the places where any of the salt is left adhering; citrate of baryta, being to a certain extent soluble in water, is soon taken up by the liquid; then add to it double its volume of alcohol 95 per cent, and pour on the filter with the first product. This being repeated a second time, all the citrate of baryta may be considered as collected on the filter. Wash this thoroughly with alcohol 63 per cent, and dry at a moderate heat. The precipitate thus obtained contains all the citric acid of the citrate in the form of citrate of baryta; but this salt is too hygroscopic to give correct results if weighed directly. It is necessary to transform it into sulphate of baryta. This is done without difficulty, by burning the filter and heating the ashes and precipitate with sulphuric acid several times, till a constant weight is obtained. The weight of the sulphate of baryta is then noted, and from this the weight of the citric acid may be calculated within 2 or 3 milligrammes.

If free citric acid is to be estimated, a convenient quantity may be first saturated with a titrated solution of caustic soda, which gives usually a little more than the actual strength; the citrate of soda may be then treated in the manner described above, which gives a result a little below the truth, and the average between the two results will be within 1 or 2 milligrammes of the truth.

If it is proposed to estimate the citric acid of a citrate of bases other than the alkalies, soluble or otherwise, the operation is to be conducted in this manner:—

A certain quantity of the salt, from 1.50 to 2.50 grms., is heated carefully with a solution of caustic soda or potassa in excess; the heat must be applied long enough to precipitate the base thoroughly, but not enough to alter the citric acid into aconitic, oxalic, or any other derivative; the liquid is then filtered as usual, and exactly saturated with acetic acid; after which it is treated as an ordinary alkaline citrate. For obvious reasons the saturation must be as perfect as possible.

The solution of acetate of baryta used for these precipitations may be prepared by saturating pure acetic acid diluted, with an excess of carbonate of baryta, heated to ebullition, adding some alcohol when cold, and filtering. This solution may be titrated so as to contain a certain percentage of baryta, say 5 per cent, in order to facilitate its use. The addition of alcohol insures its keeping unchanged for an unlimited period.

I am aware that none of these methods can be applied to the estimation of citric acid in those citrates the base of which is soluble in alkalies. These require a peculiar modification, of which I intend to treat another time.

As illustrations, I will describe a few analyses performed by my method.

Estimation of Free Citric Acid.

A certain quantity of crystallised citric acid containing 4 equivalents of water, unknown to me, was weighed at

my request by a friend, and dissolved in 10 c.c. of distilled water. A titrated solution of caustic soda, added till saturation, indicated 0.877 of citric acid. The neutral citrate of soda thus obtained was treated in the manner above mentioned by acetate of baryta; the citrate of baryta was transformed into sulphate, and this salt repeatedly ignited was ascertained to weigh 1.518 grms.

To calculate from this the weight of citric acid we establish the proportion—

$$\begin{aligned} 201 : 349.5 &= 1.518 : x \\ \text{or } \log. x &= \log. 201 + \log. 1.518 - \log. 349.5 \\ x &= 0.873 \end{aligned}$$

The average between the two valuations would be 0.875. The actual weight of the citric acid had been 0.875 grms.

Analysis of Citrate of Bismuth.

This citrate of bismuth is the salt obtained by precipitating acid nitrate of bismuth by a neutral alkaline citrate. It is insoluble in water, and may be obtained pure without difficulty.

Two grms. of this salt were taken, suspended in water, and decomposed by an excess of caustic potassa at a moderate heat, slowly increased till the boiling-point was reached. The precipitate of anhydrous teroxide of bismuth, well washed and dried, was found to weigh 1.122 grms. The washings were collected together, saturated with acetic acid, treated by acetate of baryta and alcohol, as already mentioned, and the citrate of baryta, thus separated, yielded 1.674 grms. of sulphate, which corresponds to 0.790 of citric acid. The balance 0.09 represents the equivalents of water and the loss. Hence we may figure the result thus:—

Teroxide of bismuth ..	1.122	1 equivalent.
Citric acid	0.790	1 "
Water	0.086	2 "
Loss	0.002	
	2.000	

Or in other figures—

Teroxide of bismuth ..	232
Citric acid	165
Water	18
	415

From this, I think the formula of the insoluble citrate of bismuth may be safely said to be—

Double Citrate of Bismuth and Ammonia.

This combination is obtained in two forms—in solution and in scales. In solution it may be either acid, alkaline, or neutral; in scales it is always acid, on account of the loss of some ammonia during evaporation. It is very extensively used in medicine; unfortunately its solution is rather unstable.

The analysis of this salt presented no difficulty: 2.085 grms. of the insoluble citrate of bismuth were weighed in a small porcelain dish, a little warm water added, and a small piece of litmus-paper allowed to float on it. Then a titrated solution of ammonia, containing 0.26 grm. of ammonia to the 100 measures, was cautiously added, the mixture being stirred all the time. As the last drops of the 100 measures fell into the porcelain dish, the litmus-paper, red until then, turned blue, and at the same time the liquid became perfectly clear. Thus by synthesis this gives for the neutral citrate of bismuth and ammonia the following formula:— $2\text{NH}_3, \text{BiO}_3, \text{C}_{12}\text{H}_5\text{O}_{11} + n\text{HO}$. That is, two equivalents of ammonia, and one of bismuth teroxide saturating one equivalent of citric acid, the proportion of water being undetermined.

The analysis of the salt in scales was effected thus:—2.302 grms. of the ammonio-citrate of bismuth in scales (as it is commonly called) were dissolved in a little warm

water, and a small piece of blue litmus-paper was made to float on it. The litmus-paper turned red immediately. Then, the same titrated solution of ammonia already mentioned was added carefully till saturation. Of this, 25 measures were necessary, corresponding to $\frac{1}{2}$ equivalent. This demonstrated already that the quantity of ammonia contained in the salt was 1 $\frac{1}{2}$ equivalents.

The liquid was then decomposed by caustic potassa in excess, and the operation conducted precisely in the manner described for the analysis of citrate of bismuth. The following numbers were obtained:—

Teroxide of bismuth	1.170
Citric acid	0.823

The quantity of ammonia being already known, the compound may be re-constructed thus:—

Teroxide of bismuth ..	1.170	1 equivalent.
Citric acid	0.823	1 "
Ammonia	0.122	1 $\frac{1}{2}$ "
Water	0.180	4 "
Loss	0.007	

2.302

Or, in chemical symbols—

I must say that in this salt I believe the proportion of ammonia may vary slightly, according to the mode of evaporation; it cannot fall below 1 $\frac{1}{2}$ equivalents, however, without causing a decomposition of the salt.

Analysis of the Double Citrates of Bismuth and Potassa, Soda, and Lithia.

I believe these combinations have neither been mentioned nor obtained yet by any body. Besides their interest in a chemical point of view, I think they will become of some importance in medicine, on account of their greater stability compared to the analogous ammonia salt. Of this I will treat another time.

The potassic and sodic citrates of bismuth are obtained easily by adding 2 equivalents of the caustic alkalies to 1 equivalent of the simple citrate of bismuth suspended in water, moderate heat being applied. They require, however, a little more care than the corresponding ammoniacal combination; for any excess of soda or potassa is liable to precipitate some of the metallic oxide, a decomposition which ammonia will not cause under any circumstances.

The double citrate of bismuth and lithia is prepared by adding 2 equivalents of carbonate of lithia to 1 equivalent of the simple citrate of bismuth, heat also being applied.

The following are the formulæ of these double citrates:—

Not having obtained yet any of these salts in scales, I cannot state the equivalent of HO.

I have remarked, also, that the 2 equivalents of alkali necessary to form the neutral citrate need not be of the same base; thus 1 equivalent of soda and 1 of lithia form a neutral soluble citrate with 1 equivalent of citrate of bismuth, &c.

All these double citrates are soluble and uncrystallisable.

My study of the citrates is very far from being completed; but I have collected facts enough to justify me in proposing to divide the different citrates into three classes.

In the first class I would place all the various simple citrates, where the acid is combined with 1, 2, or 3 equivalents of one base. These are so well known that little need be said about them.

The second class would comprehend the double citrates, that is, those salts in which 1 equivalent of citric acid is

combined with 2 equivalents of an alkali and 1 equivalent of another base, generally metallic. The simple citrate of this base is in most cases insoluble or little soluble in water, while the double citrate is soluble in all proportions. The various double citrates of bismuth mentioned in this paper may be considered as types of this class. This class of salts is very large; a great many are known and mentioned, such as ammonio-citrate of bismuth, ammonio-citrate of iron, potassic-citrate of magnesia, zinc, &c. The composition of none of them, however, is stated anywhere to my knowledge.

The *third class*, or quadruple citrates as I propose to call them, is not so well known, the only one being, I believe, the soluble pyrophosphate of iron discovered in 1856 by E. Robiquet, my late friend and employer. I consider these salts as a combination in which an alkaline neutral citrate plays the part of a base, and a peculiar metallic salt the part of an acid. I have already collected several facts in support of this theory, but they require proper elucidation and study to prove it conclusively. I will only mention that, in following up this theory, I have already discovered the following new combinations, which I place in the third class:—

Phosphate of sesquioxide of iron,	
Hypophosphate "	"
Valerianate "	"
Arseniate "	"

in combination with the neutral citrates of potassa, soda, lithia, and ammonia.

All these salts are uncrystallisable, soluble in water in all proportions, little so in alcohol; they have no taste of iron; all are decomposed by direct sunlight, and all have a greenish colour, varying from bright apple-green to dark olive-green. The valerianate of iron, possessing by itself a bright red colour, forms, with citrate of ammonia, a combination of an extremely bright green colour.

I have obtained all these salts in solution, and some of them in scales. The solutions keep very well for a long time if about 16 per cent of alcohol be added and direct sunlight excluded: they may be preserved, also, by the addition of enough sugar to give them the strength of official syrup (a little less than twice their weight).

I have not analysed any of them yet, but will publish the results of their analysis as soon as satisfactorily obtained.—*American Chemist.*

ON THE EVIL EFFECTS OF THE USE OF ARSENIC IN CERTAIN GREEN COLOURS.*

By FRANK W. DRAPER, M.D.

(Continued from p. 41).

V. Paper-Hangings.—Important as are the topics which have thus far engaged our attention in the study of the arsenical greens and of the possible dangers incident to their use, they appear to have always been considered as of less significance than those relating to arsenical paper-hangings. Since Professor Gmelin, of Heidelberg, called attention, in 1843, to what he deemed the deleterious effects of living in rooms whose walls were decorated with green paper, the subject has been repeatedly investigated in all its relations. Distinguished scientific authorities in Germany, France, England, and America have regarded the matter as one eminently deserving careful consideration, and the unanimity which characterises the results of their studies can leave little room for doubt in unprejudiced minds concerning the harm which may ensue, under certain conditions, from the use of arseniferous wall-paper. Other observers, comparatively few in number, who have arrived at negative or at wholly dissenting conclusions,

seem to have based their experiments on wrong premises, or to have shown partiality in their statements.

As a result of the unequivocal warnings published by physicians in past years, the use of the arsenical paper-hangings became for a time and in some degree unfashionable. But the dictates of fashion are capricious, and are not long mindful of the protests of science. The public has forgotten the experiences of ten years ago, and the poisonous paper-hangings are displayed in the shops to-day with the same fascinations of colour, design, and finish that has characterised them in the past. In every store which the writer has visited in the course of these investigations, specimens of the paper have been obtained which, on being tested, exhibited the presence of the arsenical pigment in a greater or less degree.

This renewal of a practice which has been condemned heretofore in terms of unconditional disfavour justifies a renewed investigation of the subject. It is a matter of no ordinary importance to a community to know that, by the use of paper-hangings of a certain colour, the health of individuals is seriously jeopardised. It is not a pleasant thing to realise that the very means we take to make our homes more cheerful may become the direct source of impaired health, and that the beautifully artistic designs which decorate the rooms in which we live or sleep may be the subtle agencies whereby the sum of human misery is increased.

It ought to be remembered, at the outset of this inquiry, that all paper-hangings which are green are not to be condemned as poisonous. Not a small proportion owe their tint to other pigments than the arsenite of copper. And this fact that the arsenical papers are found in comparatively good company adds another element of importance to the subject, suggesting the greater need of discrimination. Moreover, with regard to paper-hangings which are actually arsenical, it will be perhaps exceptional to find specimens coloured to any great extent with the unadulterated arsenite or aceto-arsenite of copper, as distinguished by the purity and brilliancy of the green tint, because it is the custom of the manufacturers to modify the shade of green by the addition of substances which shall make the tint darker or lighter to suit varying tastes; yet the primary pigment contains arsenic, whose presence can be detected only by the chemist's test, and not by any distinctive physical appearance. To proscribe a wall-paper, therefore, because it is green, and without further test to condemn it, even though it be found on the room of a confirmed invalid, would be hasty judgment, while, on the other hand, cases undoubtedly occur in which obscure and distressing symptoms are due to arsenical poisoning, the agent being concealed in a tint bearing so distant a resemblance to the brilliancy of pure emerald green as to readily escape detection.

In the manufacture of paper-hangings, no provision is made with a special view of anticipating and preventing any possible harm which may result from the employment of the arsenical pigment. Whether the pattern be a plain or a figured one, the colouring matter is made to adhere to the paper by means of size. The emerald green, generally adulterated with Paris white or some other neutral agent in order to obtain the desired shade, is mixed with warm water in which size has been dissolved; in this process of colour-mixing the workman often uses his hands, plunging the fore-arm nearly up to the elbow into the sieve through which the ingredients are passed. When the colour is prepared, it is applied to the surface of the paper by means of a series of brushes worked by machinery, and a uniform coating is thus quickly secured. Passing from this machine, the paper is suspended in long loops from sticks which rest on a slowly moving, endless chain arranged near the ceiling; being carried thus in loops the length of a long room whose temperature is maintained at a high degree by steam apparatus, the paper becomes thoroughly dried. If it is to be "satined," or glazed, it is passed through a series of dry brushes which revolve with great rapidity. The figured patterns are printed by

* From the "Third Annual Report of the State Board of Health of Massachusetts."

two methods. The slower, but more accurate process, and therefore better adapted for fine work, is by hand-printing, the pattern being secured by blocks, a colour at a time, precisely as in the earliest days of paper-hangings. But most of the printing is done by machinery not unlike that used in calico printing. The paper is passed against a series of revolving wooden cylinders, on whose surface are raised figures corresponding respectively with the individual shades of colour to be observed on the paper when finished; each cylinder is fed with its own pigment by means of a revolving belt of fine woollen, which passes through a trough of colour. The variety called "flock-paper" requires a special process to give it the well-known roughened or velvety aspect. The flock consists of the finely-divided shreds of waste woollen cloth. The stock is scoured and dyed. It is then stove-dried and ground to a fine powder; the requisite degree of fineness is secured by successive sifting in a bolting apparatus. A quantity of this woollen dust is enclosed in a large chest or drum, the bottom of which consists of sheep-skin or of strong cloth. The paper is first prepared with a layer of size and then of varnish. If the paper is to be a plain flock, this adhesive material is spread uniformly; if figures are desired, the pattern only is printed in varnish. Successive portions of the paper are passed into the drum, and, the bottom of the chest being beaten, the flock dust is raised to settle on the still moistened and adhesive surface, where it is allowed to dry.

From this description it will be seen that the arsenical paper-hangings include three well-defined varieties, according to the methods used to attach the colouring matter to the surface of the paper with greater or less degree of permanency; they are unglazed, or sated, or flock. These comprise all grades, from the most costly to the cheapest, and vary from the plainest surface to the most elaborately figured designs. In some there is a thick coating of the colour, loosely applied, either for a perfectly undecorated paper or to serve as a ground on which to impress the various figures. In others, only isolated or small patterns of foliage contain the green pigment. Of all the varieties, however, those which have an unglazed surface are the most likely to produce harm, since in this class the colour is only moderately adherent, and is removed by the slightest friction. The glazed papers are less open to this objection, because the process which gives the polish serves also to fix the pigment more securely. From such a surface the green dust would not escape readily, until, after long wear or by frequent dusting abrasions in the glazing were produced. The flock papers occupy an intermediate place between the two varieties alluded to. The wool which constitutes the flock is generally of a dark green colour from vegetable dyes; and if the arsenical pigment is used, it is found in the ground tint on which the flock is laid, or in the green-figured foliage formed in the intervals. The flock, as primarily prepared, is not poisonous; but it may become so, since it is easily detached from the paper, and may bear away with it particles of the subjacent colour.

The quantity of the poisonous colour which is used upon these papers varies exceedingly, of course, but occasionally it is found in very large amount. Professor Bacon asserts: "Frequently so much as 50 or 60 grains of the arsenical pigment is spread on each square foot of the paper."* In a specimen examined by Dr. Halley, nearly a drachm of the colour was found in the square foot;† and Dr. Taylor states the results of his analyses to vary from 28 to 70 grains in the same surface.‡ Two samples of the paper are exhibited; they have been analysed for the writer by Mr. Pearson at the Institute of Technology. The lighter-coloured specimen contains 5.42 grains of arsenic in each square foot. The paper also shows under what a deceptive guise the arsenical pigment may appear. The second sample, which is

typically arsenical, and which represents the colour in its purity, has 29.32 grains of pure arsenic in each square foot. Taking the average of these results, a room of ordinary dimensions, decorated with arsenical paper-hangings, would hold on its walls considerably more than a pound of a poisonous colouring matter containing half its weight of arsenic.

The question, however, which most concerns us is, Does the presence of this pigment, in such large amount, on the walls of rooms habitually occupied by day or night exert any deleterious influence on the health of the occupants? Can an agent, avowedly very poisonous when swallowed, become disengaged in any way, directly or indirectly, from the surface to which it is but loosely attached, and contaminate the atmosphere to such a degree as to produce, by slow but continuous absorption, unmistakable symptoms of injury? There will be those who, through incredulity or from motives of interest, will cite cases of perfect immunity under such conditions, and will maintain that the brilliant colour is inert, even granting the presence of arsenic, and that there is nothing in the paper-hangings in question to arouse alarm or suspicion. The alleged cases of illness from this cause ought rather, they say, to be attributed to bad ventilation and other abuses. Nevertheless, when the many recorded and well authenticated instances of impaired health, including a considerable number which have terminated fatally, are examined impartially, little room is left for scepticism. The cases are too numerous and too unequivocal to be thrown aside, and constitute a mass of evidence which cannot well be refuted. It will be unnecessary to cite a great number of these cases here. The columns of the medical and of the general press of the last ten years contain the histories of numerous instances; and of these only a few of the typical ones will be quoted as illustrations.

Dr. Halley, of London, has reported a case of arsenical poisoning in which he was himself the victim. His library walls had been covered with a newly-made, rich, emerald-green flock-paper. Shortly after the work was finished, he commenced to occupy the room every evening for some five or six hours, a single gas-burner supplying the light. After a few days he began to suffer considerably in health; there was constant headache, dryness of the throat and tongue, with internal irritation. After three weeks of this experience, he became completely prostrate, not yet, however, suspecting the cause of his malady. Partial paralysis of the left side supervened. His condition obliged him to discontinue his studies in his library, and coincident with this intermission he began at once to recover. But as soon as he re-commenced his labours the symptoms recurred. His attention was now called to the paper on the walls of the apartment. It was found to contain nearly 60 grains of Scheele's green to the square foot. The air of the room was likewise tested, and distinct crystals of arsenic were obtained from the dust. The paper was at once removed, and there was no further trouble.*

In 1862, a case of fatal poisoning under the conditions in question occurred in the suburbs of London, the victim being a child. The cause of death was made the subject of an investigation before a coroner's jury. In the course of the evidence, it transpired that the deceased was the last of four children who had died within a period of two months under exposure to the poison contained in the paper-hangings of the room they habitually occupied. They had all been attacked in the same manner, the prominent symptoms being referred to the throat. The colour was loosely applied, having no glazing. It was very deliquescent; at 50° it was quite damp, and the stain came off on the hand like paint. Three grains of arsenic were found in a square foot of the paper. The symptoms were attributed by the surgeon in attendance, Mr. Orton, and by Dr. Letheby, who made the *post mortem* chemical examination, to arsenical poisoning.†

In a case reported by Dr. Guy, the patient being a young lady, there were observed gastric irritation, emaciation, flatulence, pain in the abdomen, loss of appetite, nausea, a furred tongue, dryness of the mouth and throat, a quick, small pulse, oppressed respiration with dry cough, failure of strength, an aversion to food and drink, a blanched complexion. Temporary absence from home brought relief to the sufferer, but it was not until after recurrences of the symptoms coincident with the return to the arsenical room that the wall-paper was suspected. The paper was removed, and a plain white paper took its place, and no further symptoms of poisoning were experienced. The workman who removed the arsenical paper was very ill the whole night and day following, "with cramps, sickness, and pain." The green paper was a glazed, watered pattern, covered with two shades of the most delicate tint.*

Dr. Hinds reports an experience not unlike that of Dr. Halley. He says:—

"In 1849 I ordered my study to be re-papered, and I selected for this purpose a neat paper, with only about two shades of green, of a bright and elegant tint. In a day or two after the room was papered I began to use it. I had a fair gas-light, and towards evening I began to read. When about an hour and a half to two hours had passed, symptoms of severe depression seized me, soon followed by a feeling of nausea and an inclination to vomit. There were occasional pains in the abdomen also, and the prostration was presently accompanied with a feeling of faintness which suspended my operations. The very same thing occurred every successive evening, when the door of the room was closed, the gas-light burning, and after I had remained about a couple of hours in the room. The unpleasant symptoms gradually subsided when I had left the room, a feeling of faintness and some stomachic derangement alone remaining."

The green pigment, on being sublimed in a test-tube, gave abundant crystals of arsenious acid. The paper was removed, and the annoyance never reappeared.†

Dr. Hinds also reports other cases under his personal observation. In one of these, a gentleman of Birmingham had two parlours papered with a bright green paper. In less than a week afterwards, both himself and his wife, previously in good health, became ill. They were in the habit of sitting in one of the rooms regularly. The symptoms complained of were great prostration of strength, headache, and a low, febrile condition, together with inflammation of the eyes (*conjunctivitis*), thirst, loss of appetite, heat and dryness of the throat, with tightness across the forehead. The great inaptitude for exertion and general prostration of the strength appeared prominent. As in the previous cases, temporary absence from home was attended with a remission of the symptoms, and the removal of the paper was followed by early and complete restoration of health. The paper was of the "flock" variety, with a profuse pattern of a light and elegant green on a flock ground, yielding, on analysis, an abundance of arsenic.‡

Dr. James Whitehead, of Manchester, has recorded an instance, which may be cited as a typical one, not only as illustrating the disease in question, but as affording an example of the difficulties sometimes experienced in determining its true character. The patient, a young man, suffered from ulceration of the gums and tonsils, violent frontal headache, great languor, nausea and occasional vomiting, inappetence for exertion, and disturbed sleep. The complaint, mild at its onset, gradually increased in severity in spite of medical treatment, and at the end of eight or ten weeks the patient was removed to the country; here he was speedily restored to health. On his return home, perfectly well, he was placed in the same room he occupied before; in the space of four weeks he was worse than ever. The drains being suspected of some indirect

influence in causing the diseased condition, they were examined, but nothing was discovered to account for the trouble. Attention was next directed to a cistern which adjoined the wall outside the patient's room, and it was re-modelled with the hope of remedying the mischief. The repairs necessary for this change required the patient to occupy another room for a fortnight; this intermission was attended with considerable relief, and he returned to his old apartment feeling much better. The former symptoms recurred with aggravated severity, and now for the first time it was suspected that the wall-paper was the source of the mischief. The paper was replaced without loss of time by one of a totally different shade, and results in every way satisfactory followed. There was no relapse of the symptoms after the removal of the paper, and the young man occupied the room without further annoyance.

The paper was a "rich green flock paper." While it was being applied, a green dust escaped freely; and afterwards, whenever the walls were cleaned, a similar powder was found on the furniture. 30 grains of the pigment yielded, on chemical analysis, 11 grains of arsenic, and it was estimated from this that the room, having a superficies of 350 square feet, held in its paper-hangings, after four years of usage, 3,850 grains, or about half a pound, of white arsenic.*

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.†

By Dr. F. CRACE CALVERT, F.R.S.

(Continued from p. 41).

Carmines Lakes.—These very beautiful pigments are prepared from a decoction of cochineal, and not from carminic acid, the animal matter which the insect contains, appearing to be necessary to their production. The mode of preparing the finest qualities is kept a secret by the manufacturers; but I will describe two processes which give very satisfactory results. The first consists in boiling one pound of ground cochineal with two gallons of water, to which has been added one ounce of alum. It is then boiled for three minutes, the liquor is allowed to settle, and, after having been kept for several days, about an ounce of a bright carmine lake is produced. For the alum employed in this process cream of tartar can be substituted. The second process consists in boiling for three hours two pounds of powdered cochineal in thirty gallons of water. To this is added three ounces of pure saltpetre. The liquor is then boiled again and left to settle. The clear liquor is run off, and after two or three weeks yields a fine carmine lake.

As these lakes are expensive, they are often adulterated with starch, kaolin, vermilion, &c. The complete solubility of pure carmine lakes in ammonia affords a ready means of detecting these adulterations.

Kermes.—This colouring-matter is also derived from a variety of *Coccinus*, which lives on the species of oak called *Quercus coccifera*. The young female animal fixes itself under the epidermis of the leaves or young shoots of the oak, in the early part of spring. As the insect grows, it gradually swells out the epidermis, covering the surface of the leaves or branches with a multitude of excrescences. During this period it deposits its eggs.

In Spain and the South of France, during the month of June, or just before the eggs produced would be hatched, the animals are removed, and destroyed by placing them in the steam from heated vinegar.

Although this colouring-matter is seldom used in England, it is extensively employed in the South of France, in Spain, Morocco, and Turkey, to dye morocco

† The Cantor Lectures, delivered before the Society of Arts. Revised and communicated by the Author.

leather, and to dye woollen cloth with that particular shade which characterises the cap called "fez," worn by the Asiatics.

If the colour is not so brilliant as that of cochineal, it has the advantage of not being changed by soap or dilute alkalies. It is also employed at Milan, Rome, and Florence to colour a very favourite beverage known as alermes. The colour-giving principle of this insect is identical with that of cochineal, and has been used as a dye in the East from time immemorial.

Gum-lac.—This is another variety of the *Coccinus*, which lives especially on the *Ficus*, or fig tree. They reproduce themselves with such rapidity and in such numbers that they entirely cover the surface of the branches of the trees on which they are deposited. Owing to a resinous fluid which they secrete, they form solid masses, which are often a quarter of an inch thick, all round the branches, and adhere very firmly to them. The natives break of these branches just before the hatching season of the animal, and expose them to the sun to kill the insect. These gum-lac twigs are sold under the name of stick-lac. Those of Siam are considered the best, those of Assam next, and those from Bengal the worst.

There are three kinds of lac in commerce—stick-lac, which has just been described, seed-lac, and shell-lac. The resinous concretion is taken from the twigs, coarsely powdered, and triturated with water in a mortar. The greater part of the colouring principle is thus dissolved.

The granular portion which remains is dried in the sun, and constitutes seed-lac. Shell-lac is obtained by melting seed-lac, and straining whilst hot. It is then dropped upon smooth stems of the banyan tree, and so runs into thin plates, which are known in commerce under the name of shell-lac.

These three lacs have the following composition:—

	Stick-lac.	Seed-lac.	Shell-lac.
Resin	68.0	88.5	90.9
Colouring matter ..	10.0	2.5	0.5
Wax	6.0	4.5	4.0
Gluten	5.5	2.0	2.8
Foreign matters ..	6.5	—	—
Loss	4.0	2.5	1.8
	100.0	100.0	100.0

The colouring matter of the insect is identical with that of cochineal and kermes, and it has been employed as a scarlet dye-stuff in the East from time immemorial.

Lac-lake and Lac-dye are preparations imported into this country from India since 1796. They are both prepared by adding on stick-lac by a weak alkaline solution, to which is then added a solution of alum. This produces a precipitate, which, when washed and dried, is ready for use. Although both these lakes are prepared with the same substances, lac-dye is considered much superior in quality. This is due to the greater care bestowed on its preparation. The details of the process are kept secret.

To dye woollen cloths with them, they are dissolved in a weak solution of vitriol, to which is added a little oxymuriate of tin, and the cloth dipped in when the liquid is near the boil. It only requires washing and finishing to be ready for market.

Some years ago Messrs. E. Brooke and Co., of Manchester, introduced a lac-dye much superior to that imported from India, which they prepare by treating stick-lac with weak ammonia, and adding chloride of tin to this solution, when a fine red precipitate is formed, which, collected, is ready for use.

Murexide or Roman Purple.—Although this colour has now been superseded by those derived from coal-tar, I call your attention to it as an example of the assistance rendered by the progress of chemistry to the art of calico-printing.

In 1776, the illustrious Swedish chemist, Scheele, discovered uric acid in human urine. In 1817, Brugnatelli found that nitric acid transformed uric acid into a sub-

stance which he called *erythric acid*, but which was afterwards named by Wöhler and Liebig *alloxan*. In 1818, Dr. Prout found that this latter substance gave, when in contact with ammonia, a beautiful purple-red colour, which he named *purpurate of ammonia*—the product known by the name of *murexide* since the researches of Liebig and Wöhler in 1857. These discoveries remained dormant in the field of pure science until the year 1851, when Dr. Saac observed that when alloxan came in contact with the hand it tinged it red. From this he inferred that it might be employed to dye woollen fabrics red, and further experiments showed that if woollen cloth, prepared with a salt of tin, were passed through a solution of alloxan, and then submitted to a gentle heat, a most beautiful and delicate pink colour was obtained.

In 1856, MM. Depouilly, Lauth, Meister, Petersen, and A. Schlumberger applied it as a dyeing material to silk and wool, and succeeded in producing red and purple colours, by mixing the murexide with corrosive sublimate, acetate of soda, and acetic acid.

For printing upon cotton, a mixture of murexide with nitrate of lead or acetate of zinc, properly thickened, was printed on the fabric, which was then allowed to dry for a day or two, when the colour was fixed by passing them through a mixture of corrosive sublimate, acetate of soda, and acetic acid.

The uric acid required for the preparation of such large quantities of murexide was obtained from Peruvian guano. The guano was treated with hydrochloric acid, and washed. The insoluble mass was then treated with nitric acid of specific gravity 1.40. When the action of the acid was completed the mass was treated with warm water to dissolve out the alloxan. It was then carefully evaporated to such a degree that it became solid on cooling. The solid mass had a brown or violet colour.

(To be continued.)

NOTICES OF BOOKS.

Air and Rain: The Beginnings of a Chemical Climatology. By ROBERT ANGUS SMITH, Ph.D., F.R.S., F.C.S., (General) Inspector of Alkali Works for the Government. London: Longmans and Co. 1872.

DALTON, the father of meteorology as well as of strictly scientific chemistry, declared in the later years of his life that chemical experiment could not distinguish the air of Manchester from the air on Helvellyn. Presently we shall see what progress has been made in chemical determination. Dr. Smith very modestly terms his work the "Beginnings" of a chemical climatology; but although most of what has been done in this department of sanitary enquiry has been commenced and carried out by Dr. Smith, his title is unfair to himself, because he has carried his investigation to the limits of present chemical science.

"Chemistry," says Dr. Smith, "has not hitherto done enough in sanitary enquiries, and it ought to be able to relieve medical men of much of their heavy responsibility, although no subject relating to health can be entirely taken out of their hands." Again, "We rush over the world, scarcely considering that the air we inhale must change at almost every step; and we build our houses, not thinking that every field has a climate of its own, unless circumstances are more nearly the same than we can hope for in our country. In extensive tracts, where soil, level, and inclination are similar, such as great prairies or steppes, there will be few changes until the borders are approached, in which case contiguity of other surfaces will produce a variation. In England, which is a comparatively small country, with much variety of soil, it is difficult to find a place where a short distance does not produce some change; and in Scotland, a still smaller and more varied country, the differences of climate are

even more striking. Indeed, every farmer studies his land in this respect; and the fields are devoted to various purposes, according to climate as well as soil." These quotations serve to show not only the importance of the investigation, but as well the acknowledgment of its importance by the investigator, of whose indomitable energy in the pursuance of his scientific convictions chemists are well aware. The Inspector under the Alkali Act is pre-eminently the one who should commence the systematic study of the subject before us, both because of his scientific attainments and the minute accuracy with which his experiments are made and recorded, telling us exactly how the matter stood when the experiments were commenced, the work done, and the result at completion.

Regnault was the first to begin to refine the study of the air, and to show the distinction in the amount of oxygen in pure and tainted air; a portion of Dr. Smith's work has been to complete and further detail the determinations. The results show the amount of difference between the atmospheres of the mountains, of great plains, and of cities. "It is true," says Dr. Smith, "that in figures this appears small; but what is the meaning of small; if we measure size by percentage it will appear small; but still smaller will appear the strychnine that destroys us, if we estimate the amount as a percentage of the weight of our bodies."

We proceed to extract from the voluminous tables some of the most general numerical results:—

Oxygen in the Air.

(Per cent, or, if read as whole numbers, per million).

	Vol. per cent.
N.E. sea-shore and open heath (Scotland)	20.9990
Tops of hills (Scotland)	20.9800
In a suburb of Manchester in wet weather	20.9800
"	20.9600
"	"
Swampy places, favourable weather, France and Switzerland	20.9220 to 20.9500
In fog and frost in Manchester	20.9100
London, open places, summer	20.9500
In a sitting-room, which felt close, but not excessively so	20.8900
In a small room with petroleum lamp	20.8400
Ditto, after six hours	20.8300
Pit of theatre, 11.30 p.m.	20.8300
In sumps or pits in a mine (average of many)	20.1400
When candles go out	18.5000
The worst specimen yet examined in a mine	18.2700
Very difficult to remain in for many minutes	17.2000

"Some people," continues Dr. Smith, "will probably enquire why we should give so much attention to such minute quantities—between 20.980 and 20.999—thinking these small differences can in no way affect us. A little more or less oxygen might not affect us; but supposing its place occupied by hurtful matter, we must not look on the amount as too small. Subtracting 0.980 from 0.999, we have a difference of 190 in a million. In a gallon of water there are 70,000 grs.: let us put in an impurity at the rate of 190 in 1,000,000; it amounts to 13.3 grs. in a gallon, or 0.19 grms. in a litre. This amount would be considered enormous if it consisted of putrefying matter, or any organic matter usually found in waters. But we drink only a comparatively small quantity of water, and the whole 13 grs. would not be swallowed in a day, whereas we take into our lungs from 1000 to 2000 gallons of air daily. The detection of impurities in the air is, therefore, of the utmost importance, and it is only by the finest methods that they can be ascertained in small quantities of air, even when present in such quantity as to prove deleterious to health."

The fraction of a per cent usually considered to be an extremely small quantity, and, if belonging to the second decimal place, unworthy of regard, Dr. Smith shows to be of the highest importance, from the fact that the amount of sulphuric acid in the air is still less than of the carbonic acid, and yet a greater effect is produced on

the atmosphere than is indicated by the amount shown in the oxygen or carbonic acid volumes. Thus Dr. Smith concludes that we must pay attention to the number in the second place for oxygen, and that in the case of carbonic acid we must attend to the third even now, and for scientific purposes even to the fourth, or one part in a million. 0.0314 and 0.0400 per cent may mean 314 and 400 in a million: the difference is 86 in a million, a quantity perceptible to the senses; while we must know that the effect of poisons on health is not in proportion to the effect on the sensations. Continues Dr. Smith, "Let us consider what is meant by this 86 in a million. A room twice the size of one not unusual, or two 30 feet long, 24 wide, and 15 high, will contain 21,600 cubic feet, or 37 324,800 cubic inches. If we introduce 0.0086 per cent, we bring 3209 cubic inches of carbonic acid into the room, which will be considered a large amount if put together in vessels: it is nearly 12 gallons. During fogs there will be an addition of nearly five times the amount = 60 gallons, or 405 in a million. If we take the numbers found in a very moderately close building, we add 1235 in a million, or fourteen times the first amount, or 168 gallons. If we make the room as close as a crowded theatre, taking the number given for one in London 0.320, we add 2831 in a million, or 377 gallons. And when we come to the state of air in mines we have various numbers, in a few instances rising to more than 2 per cent—nearly a million cubic inches, which would be 578 cubic feet for the supposed room, which does not differ far from this in which I now speak (the Meeting-room of the Literary and Philosophical Society of Manchester)."

The air collected at various stations is contained in a bottle of about 2000 c.c. capacity, or nearly two quarts. About a tenth of a cubic foot of the air is washed with the purest water (previously tested), this water being then submitted to the process for testing waters as given by Messrs. Wanklyn, Chapman, and Smith. The amount of air taken is, of course, accurately measured; and with reference to the organic matter, or even of inorganic salts, many bottles full are necessary. But there is so much new and important material for thought in all the experiments Dr. Smith has made, that to give an extract of his method of working would lead us beyond the limits of a book notice.

Still there is one more quotation to be rendered before we can close this admirable book. In speculating on the dispersion of organic germs, Dr. Smith says:—"We have many people so afraid of this organic matter of the air, and of all its floating particles, that they would like to filter it all out, and breathe the gases pure. We must not allow our fear to go too far. We have no reason to be sure that air free from floating particles would be wholesome; we have only the proof that, if there is an excess of some kind, it is unwholesome. Apparently everyone can breathe air tainted with any disease without being hurt, if the taint is small enough. Inconceivably small particles injure; but we must learn to divide even the inconceivably small. We can bear a larger amount of taint if it is diluted enough. Dilute sufficiently the air of a hospital, and infection ceases. One short time of the infected air produces disease; a long period of the diluted air produces none, although the number of particles that must pass over a certain spot must be much greater in the long time than when the stronger mixture passes in the short time. We learn from this that the amount that does injury is not infinitesimal; there must be a certain quantity. I do not doubt that we shall measure that readily: we can readily measure the amount of ammonia and organic matter in the infectious and non-infectious atmospheres. . . . I do not feel hopeless of being able to say that in a scarlet-fever atmosphere there must only be so much nitrogenous organic matter and so many germs, otherwise infection will be certain."

Of the data of the second portion of the work, that

on Rain, we have already spoken in our notice of the Report under the Alkali Act, in which the subject-matter was given.

Not only the chemist will be interested in this work of Dr. Smith's; it appeals to the consideration of everyone, that is, of everyone who cares for health and comfort.

Proceedings of the American Pharmaceutical Association at the 19th Annual Meeting held in St. Louis, Mo., September, 1871. Philadelphia: Sherman and Co., Printers.

THIS large volume contains in the first place the Minutes of the Nineteenth Annual Meeting; even these alone contain a large and highly valuable amount of information on various subjects relating to pharmacy, pharmacognosy, and kindred subjects. Next we meet with the reports of various committees, from which it appears that chemistry is more and more appreciated by the American pharmacists, a fact still better illustrated by the contents of the special and volunteer reports and essays. As we intend reproducing some of the more prominent papers and essays, it is hardly necessary to enter here into more particulars respecting a volume the contents of which speak highly in favour of the advanced state of efficiency, practical as well as theoretical, attained by the large number of American pharmacists. We should wish to see this volume and its predecessors in the library of every pharmacist in this country as a kind of annual cyclopædia on everything connected with pharmacy. The work is enriched with a complete general index to Vols. ix. to xvii. inclusive.

CORRESPONDENCE.

POWERFUL GALVANIC BATTERY.

To the Editor of the Chemical News.

SIR,—It may interest your readers to know that the following cheap and simple battery is nearly 50 per cent higher in potential than a Grove or Bunsen, and fully 150 per cent higher than a Daniell.

For negative, carbon packed in granulated carbon, peroxide of manganese, and precipitated sulphur; the liquid should be dilute acid—sulphuric is best. For positive, zinc in caustic potash or soda.

The potential is higher than any I know, excepting, of course, those which have magnesium, sodium, or potassium for positives.

The internal resistance is rather large; if common salt or chloride of potassium be used instead of caustic alkali, the internal resistance is much less, but the potential sinks to a little more than 10 per cent higher than a Grove. With dilute sulphuric acid on both sides, the resistance is still less, but the potential is only a little higher than a Grove.—I am, &c.,

H. HIGHTON.

2, The Cedars, Putney.

MISCELLANEOUS.

Proposed Association of Manufacturing Chemists.

—It having been proposed that the Tyne Social Chemical Society should undertake the organisation of the larger association, a meeting of the members was convened to consider the proposal. The following resolution was carried:—"The Tyne Social Chemical Society is a society of managers and chemists only, and not of manufacturers; and the Council think that the organisation of the proposed association should proceed in the first instance from the manufacturers themselves." We trust that the manufacturers, most of whom admit the desirability of the association, will at once adopt means for its formation.

University of London.—The following are lists of the candidates who have passed the recent B.Sc. and Preliminary Scientific Examinations:—*First B.Sc. Examination*—First Division. James Barnes, Owen's College; Cornelius Bulbeck, Private Study; Edward Albert Butler, B.A., private study; Frederic Chapple, B.A., Wesleyan Tr. and University Colleges; Claude Clarke Claremont, University College; Henry Wade Deacon, King's College; Frederick William Frankland, University College and Royal School of Mines; Arthur Walton Fuller, Owen's College; James Edward Harris, B.A., private study; Richard Henry Jude, Christ's College, Cambridge; John Frederic Main, private study; Arthur Milnes Marshall, B.A., St. John's College, Cambridge; Arthur Samson Napier, Owen's College; John Edward Neale, University College; Henry Shoveller Robertson, B.A., Old Trafford School and Owen's; John Charles Saunders, Downing College, Cambridge; Jas. Heber Taylor, M.A. Camb. and Oxon., Trinity College, Cambridge; James Cecil Witton, private study; William Barton Worthington, Owen's College. Second Division. Richard John Anderson, Belfast College; Frederic Harvey Barling, Owen's College; Judson Sykes Bury, Owen's College; Adam Speers, private study; Edward Worsdell, B.A., Flounders College. *Preliminary Scientific (M.B.) Examination*.—First Division. John Henry Barnard, private study; William Henry Blake, University College; James Blamey, University College; Harry Beecham Briggs, King's College; Robert Edmund Carrington, Guy's Hospital; Claude Clarke Claremont, University College; Charles Walter Evans, University College; Richard Hingston Fox, London Hospital; George Aldridge George, University College; Francis Goodchild, Epsom and University Colleges; John Benjamin Hellier, Leeds School of Medicine; George Courtenay Henderson, University College; Wilfred Francis Hopwood, Manchester Grammar School; Edwin Joseph Le Queang, St. Bartholomew's Hospital; Howard Griffiths Lowe, Queen's College, Birmingham; Arthur Milnes Marshall, B.A., St. John's College, Cambridge; Charles Arthur Mercier, London Hospital; John Edward Neale, University College; Howard Douglas Stewart, King's College; Nestor Isidore Charles Tirard, King's College; Benjamin Arthur Whitelegge, University College; James Cecil Witton, private study; William Barton Worthington, Owen's College. Second Division. Richard John Anderson, Belfast College; Albert de Winter Baker, Guy's Hospital; Richard Legg Batterbury, King's College; Henry Blake, St. George's Hospital; Judson Sykes Bury, Owen's College; Herbert Duke, Guy's Hospital; John Christian Ferrier, Guy's Hospital; Alfred Finch, Guy's Hospital; George Michael James Giles, St. Mary's Hospital; Alexander Gray, Guy's Hospital; John Gatchell Hancock, King's College; Joseph William Hunt, University College; Alfred James, University College; Richard Henry Jude, Christ's College, Cambridge; Walter Aubrey Kidd, Guy's Hospital; William Henry Maberly, Edinburgh University; Frederick Daniell Miller, King's College; Thomas Mark Pinnell, University College; Joshua Powell, University College; James Woolley Roughton, King's College; William Joseph Seward, University College; William Allason Simmonds, Guy's Hospital; Edward Arthur Snell, King's College; Arthur Bayly Vanes, Queen's College, Birmingham; Sidney Patteshall Wilding, University College.

Trial of the Pyx.—This annual trial of the weight and purity, according to Standard, of the gold and silver moneys coined at the Royal Mint during the past year, was held on July 19th at the Goldsmith's Hall, in pursuance of the provisions of the Coinage Act, 1870, 33rd Victoria, cap. 10. This trial of the Pyx is one of the most ancient customs we retain. The following extra from the first schedule of the Coinage Act, 1870, will show at a glance the delicacy of test to be observed by the jury in weighing, and assaying the various moneys submitted to their trial, and the closeness to Standard

to which the officers of the Mint are compelled to work. The Imperial weight in grains only is here given:—

Coin.	Weight.	Remedy.
Sovereign	123'27447 ..	0'20000
Half-sovereign ..	61'63723 ..	0'10000
Florin	174'54545 ..	0'72727
Shilling	87'27272 ..	0'36363
Sixpence	48'63636 ..	0'18181

The Standard fineness for gold coins is 11-12ths fine gold, and 1-12th alloy, or millesimal fineness 916'66; the remedy or margin allowed to the Master of the Mint on coinage, being millesimal fineness 0'002. For silver coin the Standard fineness is 37-40ths fine silver and 3-40ths alloy, or millesimal fineness 925'0, the remedy being millesimal fineness 0'004. Before the jurors proceeded to the laboratory to commence their operations, they were furnished with small portions of the standard trial plates, in the custody of the Board of Trade, to guide them in their assay of the coins deposited in the Pyx. The amount of gold moneys coined at the Mint from the 1st of July, 1871, to the 30th of June, 1872, was £13,298,658, out of which coins to the value of £18,718 were deposited in the Pyx, or box, consisting of 18,464 sovereigns and 508 half-sovereigns; and the amount of silver moneys so coined within the same period was £996,138, out of which coins to the value of £357 18s. 6d. were likewise deposited in the Pyx, consisting of 2508 florins, 1798 shillings, and 646 sixpences; and of Maundy moneys, two fourpences, 80 threepences, 2 twopences, and 6 one-penny pieces. The average amount of gold coined during each year is five millions, but this year, owing to many causes, the Mint has been called upon to coin thirteen millions of gold, and more than three times the amount of silver moneys coined in 1870. This enormous increase in the supply of currency has only been met by immense exertion on the part of the authorities and workmen of the Royal Mint. Besides their labours to meet the public requirements of this country and trade generally, the Mint has been called upon to coin a large amount for the Colonies. We extract the following from the verdict, which was most satisfactory to the public and the Mint Authorities, and reflects great credit on Mr. W. Chandler Roberts, the Queen's Assay Master. "We then melted the said gold coins, making altogether 71 sovereigns and 6 half-sovereigns, so taken out and weighed, into an ingot, and assayed such ingot, comparing it with the Standard gold trial plate produced by the Board of Trade so as to ascertain whether the metal was within the remedy as to fineness prescribed in the said first schedule to the said Act; and we found that there was no variation thereof from the Standard of fineness specified in the said first schedule to the said Act." (The standard is 916'66. The ingot was 916'66 exactly. Coins would be legal if they contained 918'66 or 914'66 parts of gold in 1000'00 of alloy.) We then assayed six sovereigns and three half-sovereigns separately, and we found the millesimal fineness of such sovereigns to be 916'9, 916'7, 916'5, 917'2, 916'6, 916'6, respectively, and the millesimal fineness of such half-sovereigns to be 916'6, 916'6, 916'6, respectively.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, July 1, 1872.

This number contains no original papers relating to chemistry, but we quote the titles of the following interesting memoirs:—

Optical Phenomenon Observed During an Aërostatic Journey with an Air-Balloon.—G. Tissandier.—Illustrated by a woodcut.

Observations Made During an Aërostatic Journey with the Air-Balloon Named La Lea.—W. de Fonvielle.

July 8, 1872.

This number contains the following original papers and memoirs more particularly relating to chemistry:—

Influence of Pressure on the Phenomena of Endosmosis and Osmosis.—Dr. Becquerel.

Effects of Slow Action (Action Lente) Produced During a Number of Years.—Dr. Becquerel.—This paper contains the account of the results of some experiments which prove that, by slow but continued action, curious effects may be obtained; for instance—Crystals of arragonite are formed upon a piece of gypsum (lance-shaped variety) kept in a closed vessel in a solution of bicarbonate of potassa; the gypsum has almost entirely disappeared, having become converted into arragonite. A similar piece of gypsum, placed in a solution of arseniate of ammonia, has been converted into arseniate of lime. With a solution of aluminate of potassa and gypsum, the result is the formation of glauuberite (double sulphate of lime and potassa, the latter substituted for the soda in the mineral just named). Pieces of galena, kept for twenty years in a solution of bicarbonate of potassa, have yielded well-defined crystallised carbonate of lead. When pieces of limestone were immersed into a solution of plumbite of potassa (solution of oxide of lead in caustic potassa), the result was the formation of beautifully-crystallised hydrated carbonate of lead; malachite has been obtained by the action of limestone upon nitrate of copper, converting it into subnitrate, which, in its turn, is converted into malachite by bicarbonate of soda.

Dissolving Effect of Carbonic Acid upon Carbonate of Lime. T. Schloesing.—The second instalment of a lengthy memoir on this subject; this portion is elucidated by several algebraical formulæ and tabulated forms exhibiting results of researches.

Preparation of Aniline Colours.—Ch. Lauth.—The main gist of this paper is a refutation of an assertion made by Girard and De Laire, to the effect that the industrial manufacture of the aniline colours was highly dangerous and injurious, in consequence of the use of arsenic acid. The author of this paper says that, with due precautions, there is no danger either to the workmen engaged or to the neighbourhood of the colour-works.

Observations on Girard and De Laire's Paper on the Colouring Matter Derived from Diphenylamine.—Dr. Bardsy.—This short paper is published with the view of establishing the author's priority of discovery in reference to methyl-diphenylamine, as proved also by his paper in the *Comptes Rendus*, vol. lxxiii., p. 751.

Primary Spectrum of Iodine.—G. Salet.

Compressibility of Liquids under High Pressure.—L. Caillietet.—This paper contains the detailed account of a series of experiments, the results of which we quote in the following manner:—

	Density (Sp. gr.)	Tempera- ture.	Compressi- bility.	No. of Atmo- spheres Pressure.
Distilled water free from air	1'000	8°	0'0000431	705
Sulphide of carbon	—	8°	0'0000980	607
		9°	0'0000676	174
Alcohol	0'858	9°	0'0000701	305
		11°	0'0000727	680
Petroleum oil	0'865	11°	0'0000828	610
Petroleum essence (benzoline)	0'720	10'5°	0'0000981	630
Sulphuric ether	—	10°	0'0001440	630
Sulphurous acid (fluid)	—	-14°	0'0003014	606

Analysis of a New Variety of Amblygonite from Montebas (Creuse), of the Amblygonite from Hebron (Maine, U.S.), and of the Wavellite from Montebas.—F. Pisanl.—After referring to his former researches on this subject, and also to those of Des Cloizeaux, the author states that there exist two different varieties of amblygonite, viz., the lithico-sodic of Montebas and Saxony (Penig, analysed by Dr. Rammelsberg), and the lithic amblygonite of Montebas and of the United States. The chemical composition of the Penig and Montebas varieties are quoted as follows:—Penig—Fl, 8'11; PhO₅, 47'58; Al₂O₃, 36'88; LiO, 6'68; NaO, 3'29; KO, 0'43. Montebas—Fl, 8'20; PhO₅, 46'15; Al₂O₃, 36'32; LiO, 8'10; NaO, 2'58; MnO, 0'40; H₂O, 1'10. The wavellite of Montebas consists, in 100 parts, of—Phosphoric acid, 34'30; alumina, 38'25; water, 26'60; fluorine, 2'27; total, 101'42.

Third Bichlorated Propylen.—C. Friedel and R. D. Silva.—In this lengthy memoir the authors describe the results of their researches, which led to the discovery of a new bichlorated propylen boiling at 106°, the formula of which is—

The formulæ and boiling-points of the two other bichlorated propylenes are—

General Theory of Chemical Action; Two New Acids Obtained by the Oxidation of Sugar.—E. J. Maumené.—By the limited oxidation of sugar by means of the cautious application of permanganate of potassa, the author has obtained two new acids, which

he terms hexépíc and trigenic acids; the formula of the former is $C_{12}H_{12}O_{10}$, and of the other $C_6H_6O_{10}$.

Aldehydes Condensed with Elimination of Water, or Aldanes.—J. Riban.—This lengthy monograph treats on the action of sodium and zinc upon the following aldehydes:—Acetic, valeric, benzoic, and acetone (this body is not acted upon by the metals just named at a higher temperature). The new substances which are formed from the aldehydes are termed by the author aldanes.

Thermo-Chemical Researches on the Bodies Formed by Double Decomposition.—Drs. Berthelot and Longuiné.—The third instalment of an exhaustive monograph; this part treats on the decomposition which the chlorides, iodides, and bromides of phosphorus undergo with water.

July 15, 1872.

Absence of Combustible Gases in the Fumes Emitted by the Caldeira de Furnas, at San-Miguel (Azores).—C. Sainte-Claire Deville.—The author has analysed the gases evolved with steam by the hot springs of the locality alluded to. It appears that only carbonic acid and sulphuretted hydrogen are present, whereas in the gases emitted with steam by the Geysers, in Iceland, hydrogen was found by Dr. Bunsen, and in the Lagoni of Tuscany hydrogen were detected by the author and M. Le Blanc.

Instantaneous Oxidation of Alcohol.—A. Houzeau.—By means of ozone, obtained by the apparatus invented by the author, absolute alcohol is in a few seconds converted into aldehyde and acetic acid, with formation of peroxide of hydrogen; ether is similarly acted upon by ozone.

Estimation of Urea by means of Millon's Reagent and the Mercurial Pump.—N. Gréhaud.—This physiologico-chemical essay contains the detailed description of a process of estimating urea by first converting it into carbonic acid and nitrogen, and then estimating the quantity of these gases.

This number also contains several important papers relating to physiology, geology, meteorology, and mechanical sciences.

Jahrbuch der Kaiserlich-Königlichen Geologischen Reichsanstalt,
No. 1, 1872.

This number contains no papers strictly relating to chemistry, but we quote the titles of the following important memoirs:—

Ironstone Deposits of the Styrian Iron-Works Association.—F. Ritter von Hauer.—Illustrated with a map printed in colours.

Future of the Mining Industry in Austria.—C. Baron von Beust.

Added to and bound up with this number is a small volume, bearing the title of Mineralogical Notices, from which we quote the following:—

Chemical Examination of the Gopalpur Meteorite.—A. Exner.—The per cental composition of this stone was ascertained to be:—Iron, 20.96; cobalt, 0.10; nickel, 1.80; sulphur, 1.74 (corresponding to 4.83 per cent of sulphuretted iron and 19.77 per cent of nickel-iron); silica, 37.44; protoxide of iron, 11.94; protoxide of manganese, 0.26; magnesia, 19.72; alumina, 2.52; lime, 1.60; potassa, 0.21; soda, 0.62; oxide of chromium, traces—of the last-named bodies, 28.63 per cent is soluble, and 45.67 per cent is insoluble, in hydrochloric acid.

Researches on Limestones and Dolomites as a Contribution to our Knowledge on Metamorphism.—A. von Inostranzeff.—This essay, illustrated by a large number of engravings, contains the results of analyses of limestones and dolomites from various countries.

Polytechnisches Journal von Dr. E. M. Dingler, second number for
June, 1872.

This number contains the following original papers and memoirs relating to chemistry, &c.:—

Description of a Dephosphorising Puddling Process for the Purpose of Preparing Good Malleable Iron from Pig-Iron which Contains Phosphorus.—Dr. T. Scheerer.—In the puddling process, the chlorides of calcium and sodium are used by the author for removing phosphorus from pig-iron. The quantity of the ingredients depends upon the quantity of phosphorus present in the pig-iron; supposing it is $\frac{1}{2}$ per cent, then the quantity of the chlorides to be added to a puddling charge of $\frac{3}{4}$ cwts. will be $2\frac{1}{2} \times \frac{3}{4} \times 3 = 26\frac{1}{4}$ lbs. By the application of this process, a very good and fibrous malleable iron is obtained.

Change of a Bronze by having been for a Long Time Buried in the Earth.—E. Priwoznik.—This paper contains the account of some researches made with bronze ornaments found in an ancient burial-ground at Salzberg, near Halstatt (Austria). The composition of the metal was ascertained to be—Copper, from 90 to 92 per cent; tin, 6.5 to 9; in addition to these, small quantities of iron, arsenic, nickel, silver, cobalt, lead, and sulphur. The outer layer of the objects made of this metal, and buried in the earth for a very long time, was essentially found to consist of—Sulphur, 33.22; copper, 66.77 (the formula CuS requires—S, 33.54; Cu, 66.46). A second more inner layer was found to have been converted into Cu_2S , mixed with 15 per cent of tin, which is not met with in the outer layer. The third layer was found to consist of— Cu_2S , 59.8 per cent; tin, 23.2; water, 3.4; traces of antimony and nickel. None of these crusts or layers contained any lead, zinc, or silver.

Method of Obtaining Sugar from Molasses (Beet-Root).—M. Sebor.—The extensive report on an improved method of recovering

from beet-root molasses the crystallisable sugar it contains; the process is based upon the use of saccharate of lime.

Effect of some Methods of Boiling Down Sugar Solutions in Vacuum-Pans.—E. Jicinsky.—The contents of this paper, elucidated by a series of tabulated forms exhibiting results of experiments made on the large scale, relate to practical sugar-refining.

Journal für Praktische Chemie, No. 10, 1872.

This number contains the following original memoirs and papers:—

Some New Derivatives of Albumen.—O. Loew.—Very-quickly-dried albumen has been treated with pure monohydrated nitric acid, care being taken to cool the mixture; the result is the formation of trinitro-albumen, the formula of which (that of albumen being taken as $C_{72}H_{108}N_{16}SO_{22}$) is—

This substance is a yellow-coloured, tasteless, solid body, insoluble in water, alcohol, and ether, soluble in dilute alkaline liquids without decomposition, and precipitable from these solutions by acids; it is decomposed and carbonised by heat. This compound forms salts with lime and lead; the latter combination contains 31.01 per cent of lead. Another compound obtained by the author is oxytrinitro-albumen, a yellow-coloured solid substance, soluble in lime-water, and precipitable therefrom by means of alcohol.

Quantity of Water Contained in the Protosulphate of Iron and Ammonia.—Dr. E. Fleischer.—This essay reviews at length the results of the researches of Dr. Rheineck on this subject, and also contains the results of the author's experiments, which lead to the formula $FeOSO_3 \cdot NH_4OSO_3 + 6aq$ for the protosulphate of iron and ammonia.

Preparation of Propionic from Lactic Acid.—Dr. A. Freund.—This lengthy essay contains an account of a series of experiments made with the view of obtaining propionic acid directly from lactic acid by means of hydriodic acid. The author enters into a lengthy discussion on the by-products which are formed in this operation, and also on some of the derivatives of the propionic acid.

Chemical Composition of Maxite.—H. Laspeyres.—This paper treats on a new mineral, named maxite, found in the lead-mine of Mala-Culzetta (Island of Sardinia), and consisting, in 100 parts, of— CO_2 , 8.082; H_2O , 1.866; SO_3 , 8.140; PbO , 81.922. Formula— $5(PbO \cdot SO_3) + 9(PbO \cdot CO_2) + 4PbO \cdot 5HO$.

Oxysulphide of Carbon.—F. Salomon.—The contents of this essay may be summarised as follows:—The salts obtained by Debus from xanthogenic acid ether, and by Bender from oxysulphide of carbon and alcoholic potassa solution, are identical, and are composed according to the following formula:—

The decomposition of the last-named salt, by means of hydrochloric acid, yields pure oxysulphide of carbon; this body may be prepared indirectly from oxide of carbon and sulphur, by causing the crude oxysulphide to be absorbed by alcoholic potassa solution, and next treating the ensuing crystalline compound with hydrochloric acid. It is not probable that there exist two isomeric oxysulphides of carbon.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 13,
1872.

On some Ketons.—E. Schmidt.—This exhaustive monograph treats at great length on the following bodies:—Aceton, CH_3COCH_3 , boiling-point 56° . Propion, $C_2H_5COC_2H_5$, 100° . Butyron— $C_3H_7COC_2H_5$,

144° . Valeron, $C_4H_9COC_2H_5$, 181° to 182° . Capron, $C_5H_{11}COC_2H_5$, 220° to 221° . Enanthon, $C_6H_{13}COC_2H_5$, 264° . Caprylon— $C_7H_{15}COC_2H_5$,

178° . Methyl-capron, $CH_3COC_2H_5$, 155° to 156° .

Contribution to the History of the Phosphurets of Iron.—C. Freese.—While calling attention to Sidot's phosphuret of iron (see *CHEMICAL NEWS*, vol. xxv., p. 299), the author states that some five years ago he pointed out that such a phosphuret of iron (Fe_3P) does not exist (*Pogg. Ann.*, bd. cxxii., p. 225), and the non-existence of this substance also upsets the theory of Maumén.

Estimation of Manganese in Pig-Iron, Steel, and Malleable Iron.—F. Kessler.—Reserved for full translation.

Reduction of Isoxylol and of the Aromatic Hydrocarbons in General.—F. Wreden.—After first referring at some length to the researches of Drs. Baeyer and Berthelot, the author states that he succeeded in reducing isoxylol by the aid of red phosphorus (amorphous) and concentrated hydriodic acid, these substances being placed in strongly-made glass tubes, which, after having been sealed, were heated for the first twelve hours to 170° , and for another twelve hours to 240° . The result of this operation, followed by a complicated process of purification, is the formation of a hydrocarbon, a mixture of C_8H_{10} and C_8H_{12} , in the proportion of 84.9 per cent of the former and 15.0 per cent of the latter.

Asophenylene from Para-Asobenzoic Acid (Azodracrylic Acid).—A. Claus.—It appears that the asophenylene obtained from para-asobenzoic acid is identical with that obtained from asobenzoic acid. Azodracrylate of lime yields, by dry distillation, a solid product, which, after having been purified, exhibits yellow-coloured needle-shaped crystals, fusing at 171° , and soluble in alcohol, water, and ether.

Action of Cyanide of Potassium upon Iodide of Allyl.—A. Olas.—This paper contains the account of the results of some experiments which are not yet completed, from which the author concludes that, by the reaction of cyanide of potassium upon iodide of allyl in sealed tubes, an acid is formed which is identical with pyrotartaric acid.

Indications of the Mercurial Calorimeter.—J. Thomsen.—The contents of this lengthy essay are chiefly written to prove that the mercurial calorimeter cannot yield constant and reliable results, and that therefore the experiments made by Favre, Valson, and others with this instrument, and the conclusions drawn from these experiments, are not correct.

Detection of Chlorine, Bromine, and Iodine in Organic Substances.—F. Beilstein.—The organic substances which contain these halogens—for instance, chloroform, iodomethyl, chlorotoluol—are ignited in the blowpipe-flame, after having been placed on a small quantity of oxide of copper (kept by means of a small loop of platinum wire). The oxide of copper and halogen-containing organic substance yield a peculiar green or blue colouration to the blowpipe-flame.

Allyl-Alcohol Cyanide.—B. Tollens.—By causing a current of cyanogen gas to be absorbed by allyl-alcohol while warm, the author has obtained allyl-alcohol dicyanide, $C_2H_5(CN)_2OH$, a colourless fluid boiling at 151° .

Crystalline Forms of Dibenzyl and Stilben.—Th. Zincke.—A purely crystallographical essay, illustrated by several woodcuts.

On Terpen-Bibromide.—R. Biedermann and A. Oppenheim.—Terpen-bibromide yields, by oxidation with chromic acid (bichromate of potassa and sulphuric acid), terephthalic acid and a small quantity of a camphor-like substance containing bromine, probably the monobromhydrate oil of turpentine, $C_{10}H_{17}Br$.

Cymol from Oil of Turpentine and from Essential Oil of Lemons.—A. Oppenheim.—This essay contains the detailed account of a series of experiments to ascertain the real constitution of the essential oils by preparing from the same cymols. The cymols of terpen and citren boil respectively at 176° and 179° . The products of oxidation of cymol from terpen and citren are identical, being chiefly terephthalic acid.

Artificial Formation of Camphor.—A. Oppenheim.—While oxidising terpen-cymol, the author obtained a small quantity of a solid body which, on being analysed, proved to be camphor, which has thus been synthetically formed.

Some Derivatives obtained from Solid Dibrom-Benzol.—V. Meyer and C. Wurster.—This exhaustive monograph is divided into the following sections:—Action of ammonia upon nitro-dibrom-benzol; phenyl-diamine from bromnitro-amidobenzol.

Formation of Sulphuric Acid and Urea, and the Behaviour of Taurine in the Animal Body.—E. Salkowsky.

Journal de Pharmacie et de Chimie, July, 1872.

The following original papers and memoirs are contained in this number:—

General Method of Immediate Organic Analysis.—Dr. Fleury.—The first instalment of an essay, illustrated by a woodcut exhibiting an apparatus for exhausting organic substances with ether, treating at great length on the immediate organic analysis. This part is divided into the following sections:—Estimation of water; treatment with ether.

Double Fusion-Point of a Vegetable Wax obtained from Japan, and on the Application of that Wax in Pharmacy.—Dr. C. Roucher.—The wax here alluded to is the product of the *Rhus succedaneum*, and is now a common article of commerce. It is harder than bleached bees'-wax, but more readily fusible. The fusing-point is stated to be at from 40° to 42° ; but, on experimenting with two different samples, the author found that in reality the wax has two different fusion-points, for, on being heated cautiously from 40° to 45° , it does not become liquid, but simply softens, and remains opaque. On being further heated from 45° to 50° , it becomes transparent without becoming quite fluid; at 54° , however, the wax is quite molten. If suddenly heated to above its fusion-point, and, after having been somewhat cooled, it is placed in water at 42° , it again fuses, becoming quite fluid. The fusion-points are therefore 42° and 54° . Japan wax is not a solitary instance of this anomaly, since, according to Duffy, natural stearine (*stearine naturelle*), exhibits three modifications, fusing respectively, α at 51° , β at 63° , and γ at 66° . Bees'-wax fuses at from 62.5° to 64° .

Qualitative and Quantitative Analysis of a Mixture of Essential Oil of Bitter Almonds and Nitrobenzene.—E. Bourgoin.—The author uses caustic potassa (solid) as a qualitative test for detecting in essential oil of almonds the presence of nitrobenzene, which, if present, causes along with the potassa a reddish brown colouration of the originally yellow-coloured fluid; this colouration afterwards turns green. For the purpose of quantitative analysis, the suspected sample (some 5 to 10 grms.) is first mixed with 20 to 40 grms. of a very concentrated solution of bisulphite of soda. This mixture is thoroughly shaken in a stoppered bottle large enough to hold at least 100 grms. of fluid; ether is then added, for the purpose of dissolving the nitrobenzene, and this ethereal solution is cautiously evaporated upon a water-bath and the residue weighed. The residue (nitrobenzene) may be further converted into aniline by the aid of acetic acid and iron filings.

Study on the Fluid Secreted in Pleuritis.—Dr. Méhu.—This paper treats on a medical, rather than a chemical, subject. It appears

that the serous fluids secreted in various pathological processes all contain about the same quantity of mineral salts—viz., from 7.5 to 9 grms. to the kilo. The sp. gr. of these fluids depends in a measure upon the larger or smaller quantity of fibrine they contain.

Observations on Orange-Flower Water Distilled by means of Steam.—M. Vuafart.—It appears that the practice of obtaining the water alluded to, by passing a current of steam over the flowers placed in a suitable vessel connected with a condenser, leads to the rapid deterioration of this aromatic water; while the same remark applies to rose and other similar waters used in pharmacy. The author states that aromatic waters prepared by the old method keep far better, and are more agreeably flavoured than those submitted to the steaming process.

Estimation of Phosphoric Acid in the Presence of Iron and Alumina.—A. Adrianz.—The process of Dr. Chancel (estimation of phosphoric acid by means of bismuth) is modified by the author in the following manner:—To the chlorhydric solution of the substance in which the phosphoric acid is to be estimated hyposulphite of soda is added first, so as to reduce the peroxide of iron to protoxide; next, nitrate of bismuth is added, and the vessel containing the substances heated for about four hours upon a water-bath. The precipitate which is formed is filtered off after twenty-four hours, and after having been well washed is dissolved in nitric acid. The chlorhydric and sulphuric acids present in this solution are next first eliminated by means of nitrate of silver and nitrate of baryta, while the phosphoric acid is afterwards thrown down by means of nitrate of bismuth. The phosphate of bismuth precipitate is collected on a filter, washed, and lastly dissolved in chlorhydric acid and estimated as ammonio-phosphate of magnesia in the presence of citrate of ammonia. This process may even be employed when the substance contains fifty times more alumina than phosphoric acid; but if the proportion of alumina be very large, it is best to add to the substance a weighed quantity of pure phosphate of soda. If the iron might happen to be present in very large excess, it is necessary to re-dissolve the first bismuth precipitate and re-precipitate it a second time.

La Revue Scientifique de la France et de l'Etranger,
July 6 and 13, 1872.

These numbers do not contain any original papers relating to chemistry.

Les Mondes, July 25, 1872.

This number contains no original papers relating to chemistry, but under the heading Bibliography we notice the following work:—“Premier Siècle de l'Académie Royale de Belgique,” par M. Quetelet (grand 8vo.; Bruxelles: Hayes, imprimeur; 1872). The highly distinguished author of this work, who is perpetual secretary of the Royal Belgian Academy of Sciences, Lettres, and Beaux Arts, relates in this volume the history of the institution originally founded by the Empress Maria Theresa as sovereign of the then (1772) Austrian Netherlands.

NOTES AND QUERIES.

Glacial Sulphuric Acid.—Can any of your readers give me information as to price and names of manufacturers of anhydrous sulphuric acid?—S. R. P.

Glue to Hold against Fire.—Mix a handful of quicklime in 4 ozs. of linseed oil, boil them to a good thickness; then spread it on tin plates in the shade, and it will become exceedingly hard, but may be easily dissolved over the fire, and used as ordinary glue.—X. Y. Z.

Rendering Paper Sensitive to Electric Current.—Will you inform me what is the best solution wherewith to saturate paper so that the latter, when dry, will become sensitive (by decomposition) to electricity, showing a blue or black mark wherever the current passes? Ferrocyanide of potassium is unsuitable, because the current will not make a mark on it unless the paper is damp.—T. R.

[There is no practical method of rendering dry paper sensitive to the electric current, because dry paper is almost a non-conductor to intense currents, and quite so to ordinary quantity currents. Imperfect impressions may be obtained by employing extremely thin paper, upon which has been smeared starch-jelly (that used by laundresses), containing a few grains of potassium iodide, the electrodes being one on each side of the paper, and the current obtained from an induction-coil giving, at least, a quarter-inch spark. With clean electrodes, the first impression (the starch-jelly being dry) will probably be a good one, the second imperfect. But why not use dry ferrocyanide paper re-damped simply with water? With one electrode of iron the current from a single cell will then produce a clear impression.]

THE CHEMICAL NEWS.

VOL. XXVI. No. 663.

ON METEORIC STONES.*

By NEVIL STORY-MASKELYNE, M.A., F.R.S.

THE substantial unity of the celestial objects distinguished in common language by the names shooting or falling stars, fire-balls, and meteorites, and, further, the coincidence in many important respects of these with comets, and possibly with the zodiacal light, were suggestions made by Humboldt in the "Cosmos," which have received much confirmation from the subsequent advance of science.

The greater apparent velocity with which the ordinary meteors traverse the atmosphere as compared with that with which the less frequent larger bodies are seen to move, the marked periodicity that attends the recurrence of the former in several, and especially in two, notable cases of meteor showers, offer an apparent contrast between these classes of meteors; it is not, however, in all probability, a real contrast, for the one class passes into the other by every gradation in the magnitude of the mass or masses of which the meteor consists, and consequently in the grandeur of the phenomena which accompany its advent. If of the material composing the ordinary falling star we have never yet been able to recognise any vestiges as reaching the earth, of the meteorite, on the other hand, the mineral collections of Europe contain numerous carefully collected specimens, which are the fragments that have escaped the fiery ordeal of the transit through our earth's atmosphere, and in these we recognise masses composed either of iron (siderites), or of stones (aërolites), or of a mixture of the two (siderolites). The phenomena associated with such falls of meteoric matter have been described in very similar language by those who have witnessed them in various parts of the world, and these accounts, whether coming from European observers or from Hindoo herdsmen (of which some were read by the lecturer), concur generally in the approach of the meteorite as a fiery mass, emanating from a cloud when seen by day and exploding often with successive detonations that are heard over a great extent of country, even in certain cases at points more than 60 miles distant, but finally reaching the earth with a velocity little higher than what might be due to the motion of a falling body. Externally these meteoric masses are generally hot when they fall; sometimes, however, they are not so; the discrepancies in the accounts being explained by one authenticated case in which the mass was internally intensely cold, though at first hot externally. The fallen meteorite is invariably coated with an incrustation, sometimes shining as an enamel, generally black, but occasionally colourless where the aërolite is free from ferrous silicates; and this incrustation is seen to have been formed in the atmosphere, since it is found coating surfaces of fragments that have been severed by the explosions in the air.

Aërolites frequently fall simultaneously in large numbers, many thousands of them being in such cases spread over a surface of the country some miles in extent; and such showers of stones seem to have entered the atmosphere as a group, though their numbers must subsequently have been greatly increased by the division accompanying their detonation.

The explanation of the incrustation and of the cloud left by the meteorite, or out of which it seems to emerge, is found in the transformation into heat of the energy

actuating a body that enters our atmosphere with a motion of 12 to 40 miles a second. The velocity of the body is almost instantaneously arrested by the atmospheric resistance, and in a very few seconds the mass becomes, comparatively speaking, stationary. Its surface must, as a consequence, be immediately fused, and the melted matter would be flung off from it into the surrounding air, fresh surfaces continually affording new fused material to form the cloud of, so to say, siliceous spray that lingers along and around the path of the meteorite.

When the mass is small,—and in the case of meteoric showers and ordinary falling stars it cannot exceed a few ounces, and may often be but a few grains,—the whole material is thus consumed, and must ultimately fall as an unperceived, because widely-scattered, dust. The meteorite is the residue that survives this wasting action where the magnitude of the mass is more considerable. The cause of the violent and often successive explosions is probably to be sought in the expansion of the outer portions of the mass, while the interior retains the contracted volume due to the intense cold of space with which the meteorite enters the atmosphere.

From time to time these contending conditions of volume may, as in a Prince Rupert's drop, produce explosion, the heated shell in the case of the meteorite flying off in fragments from the internally cold inner core, which if sufficient velocity remain to the mass will undergo a recurrence of the same conditions of surface fusion and explosion. The loudness of the detonation is also probably enhanced by the simultaneous collapse of the air on the vacuum that would follow the rapidly moving mass.

The pitted surface characteristic of meteorites probably bears witness to a similar effect of unequal dilatation operating more especially in the freshly-broken surfaces of the mass, small fragments splintering off in this way from the cold and brittle stone under the sudden influence of intense heat.

A remark made by Humboldt, that light and meteorites are the only sources of our knowledge regarding the universe external to our world, points to the true ground for our interest in the waifs and strays of extra-telluric matter that thus fall upon our globe.

In physical as well as in chemical characters aërolites resemble at the first aspect some terrestrial volcanic rocks.

The minerals of which they are composed are nearly entirely crystalline, as is evidenced by the colours in polarised light of such as are transparent. These minerals are usually aggregated with slight cohesion, and they present in by far the greatest number of cases a peculiar spherular or "chondritic" structure.

In these the spherules are composed of similar minerals to those which enclose them, and even contain metallic iron sometimes in microscopically fine grains disseminated through them.

A section of an aërolite was exhibited by the microscope in which some of the spherules had been broken before being cemented by the surrounding mass, and in another fissures were seen which had been filled with a fused material after one side of the fissure had slid along the other; facts pointing to events in the history of the meteorite subsequent to its first formation.

The chemical composition and the mineral constitution of aërolites were illustrated by tables showing the elements met with in these bodies, and the minerals in which they were distributed. The former comprised about one-third of the known elements; among them magnesium, iron, silicon, oxygen, and sulphur were conspicuous; calcium, aluminium, nickel, carbon, and phosphorus coming next in importance, the basic elements of most importance by their amount being the same as those which are found by spectroscopic analysis to be present in the sun—and in those stars which have been the best examined.

The minerals most frequent in aërolites besides nickeliferous iron or troilite (iron monosulphide) and graphite,

* Read before the Royal Institution of Great Britain.

are bronzite (a ferri-ferous enstatite) and olivine, both of the latter being essentially magnesium silicates. Augite and anorthite also occur (more particularly in the eukritic aerolites of Rose) and some minerals unknown in terrestrial mineralogy have also been met with; such are the different varieties of Schreibersite (phosphides of iron and nickel); calcium sulphide, asmanite (a form of silica crystallising in the orthorhombic system and having the specific gravity of fused quartz), and a cubic mineral with the composition of labradorite. The crystalline form of bronzite was first determined from the crystals in a meteorite, and was found to confirm the conclusion Descloizeaux had arrived at as regards its system from observations on the distribution of the optic axes in the terrestrial bronzite and enstatite.

The question as to whence the meteorites come is one that we are not yet in a position to answer with certainty. The various hypotheses which suppose for them an origin in lunar volcanoes, or in our atmosphere, or again in a destroyed telluric satellite, or that would treat them as fragments of an original planet of which the asteroids are parts, or as masses ejected from the sun; all these hypotheses seem to be more or less precluded by the known velocities, the retrograde motion so frequently characterising meteors and meteorites, or else by the chemical conditions that, for instance, are involved in the passage of the meteorite through the sun's chromosphere. Whether meteorites move or do not move in circumsolar orbits is at present impossible to say; because, while with our incomplete knowledge we cannot to-day attach the character of periodicity to any known class of meteorites, we are not justified in founding any conclusion on a negative result with so limited a foundation.

But even if all or some of them may have been, on their encountering the earth, members temporarily or permanently of the solar system, we may with considerable probability consider them as having originally entered our system from the interstellar spaces beyond it. Such at least must be our conclusion if we are to admit the unity of the whole class of phenomena of meteorites and falling stars. For, since the orbits of the two best known meteoric streams, those namely of August and November, have been identified with the orbits of two comets, and since in regard to one of these (that of November) Leverrier has shown, with great probability, that as a meteoric cloud it entered and became a member of our system only some 1700 years ago in consequence of the attraction of Uranus, while the August meteoric ring only differs in this respect from it, that it had at a much more remote period found an elliptic orbit round the sun: we are constrained on the assumption with which we started to recognise also in a meteorite a visitor from the regions of remote space. And so far as it goes, the observation by Secchi that the November falling stars exhibit the magnesium lines is in harmony with this view.

It may, however, further be said, that the tendency of scientific conviction is in the direction of recognising the collection towards and concentration in definite centres, of the matter of the universe, as a cosmical law, rather than the opposite supposition of such centres being the sources whence matter is dispersed into space. In the meteorites that fall on our earth (certainly in considerable numbers) we have to acknowledge the evidence of a vast and perpetual movement of space, about which we can only reason as part of a great feature in the universe which we have every ground for not supposing to be confined within the limits of the solar system.

That this matter, whether intercepted or not by the planets and the sun, should to an ever-increasing amount become entangled in the web of solar and planetary attraction, and that the same operation should be collecting round other stars and in distant systems such moving "clouds" of star-dust as have been treated by Schiaparelli, Leverrier, and other astronomers, or individual masses of wandering stone or iron, is a necessary deduction from the view that we have assumed regarding the tendency of

cosmical matter to collect towards centres. But in order to trace the previous stages of the history of any meteorite, and, in particular, to determine the conditions under which its present constitution as a rock took its origin, we have only for our guide the actual record written on the meteoric mass itself; and it is in this direction that the mineralogist is now working.

But the progress is necessarily a gradual one. We may indeed assert that the meteorites we know have, probably all of them, been originally formed under conditions from which the presence of water or of free oxygen to the amount requisite to oxidise entirely the elements present were excluded; for this is proved by the nature of the minerals constituting the meteorites and by the way in which the metallic iron is distributed through them.

And one suggestive and significant fact remains to be alluded to; the presence, namely, in some few meteorites of combinations of hydrogen and carbon, with if met with in a terrestrial mineral would with little hesitation be assigned to an organic origin. A few grains were exhibited to the audience of such a body, crystallised from ether, which solvent had extracted it to the amount of about 0.25 per cent from 6 ozs. of the Cold Bokkeldt meteorite.

Similar substances have been extracted by Wöhler, Roscoe, and other chemists from this and other meteorites. It was, however, observed, as pointing to the probability of the comparatively porous meteoric stone having in this case taken up the hydrocarbon as a substance extraneous to it (possibly when in the state of a vapour), that ether extracted it entirely from the solid lumps of the meteorite; pulverisation not in any way adding to the amount obtained, or facilitating in any appreciable degree the separation of the substance.

CHEMICAL PRODUCTS OF EUCALYPTUS.

THE valuable character of this plant is becoming more and more appreciated as its properties are better known; and this is more especially the case since its first introduction into Europe from Australia by M. Ramel in 1856. In Southern Europe it is easily acclimatised, though, in districts so far north as Paris, the winter has been found too severe for it. In Australia and Tasmania it is very abundant. Its growth is very rapid; the leaves and the roots have a very great absorbent power for moisture; and this fact, together with the aromatic odour from the leaves, makes the tree peculiarly suitable for marshy and unhealthy districts.

In the *Moniteur Scientifique* Quesneville, M. Papillon discusses the various properties of *Eucalyptus*, and gives the following particulars as to chemical and pharmaceutical preparations obtained from the plant:—

M. Cloëz has studied the chemical properties of *Eucalyptus*. He first sought to know what proportion of essence of *Eucalyptus* could be obtained from the leaves. 10 kilos. of fresh leaves, taken from branches killed by frost in the end of 1867, furnished, on distillation with water, 275 grms. of essence, or 2.75 per cent. 8 kilos. of dry leaves, gathered, after a month, at Hyeres, produced 489 grms. of essence, or a little more than 6 per cent. From leaves that were completely dry, having been brought from Australia five years previously, about 1.5 per cent of essence was obtained.

This essence is a very fluid liquid, slightly coloured, and giving an aromatic odour which reminds one of camphor. Heated in a distilling apparatus, it commences to boil about 170°. The thermometer rises rapidly to 175°, where it remains till about half the product has passed in distillation. Another portion of the essence passes between 188° and 190°. By further application of heat, a small quantity of volatile liquid is obtained at a temperature slightly over 200°.

The liquid distilled between 170° and 178° is not a

pure product. On rectifying with potash and chloride of calcium, a very fluid colourless liquid is obtained, which boils at 175° , and which M. Cloëz calls *Eucalyptol*. It is much lighter than water; its density is 0.905, and it turns the plane of polarisation to the right. It is soluble in alcohol, but only very slightly so in water. Its composition, according to M. Cloëz, is $C_{10}H_{18}O$. When treated with nitric acid, one of the products of the reaction is a crystallisable acid, probably analogous to camphoric acid. Another product, obtained by distillation of *eucalyptol* with phosphoric anhydride in a retort, is *Eucalyptene*, a hydrocarbon with the formula $C_{10}H_{18}$. A further product, obtained by the action of phosphoric anhydride, is called by M. Cloëz *Eucalyptolene*.

Besides the essence *eucalyptol*, to which the *Eucalyptus* largely owes its medicinal properties, it contains a solid, resinous, bitter principle, little known as yet, from which the leaves derive their febrifuge qualities.

The following preparations, &c., are at present manufactured from *Eucalyptus* :—

(1). The essence already spoken of, and which is administered in doses of a few grms. in the form of globules.

(2). Leaf powder, which contains all the active principles of the plant (essence, tannin, bitter principle), and which is prescribed in doses of 4, 8, 12, and even 16 grms. daily.

(3). The infusion and decoction of the leaves. With half a leaf (about 1 grm.) it is possible to aromatise three or four cups, affording a good substitute for tea, employed as a stimulating drink. For topical applications, 8 grms. in decoction, in a litre of water, forms a liquor well charged with the principles indicated.

(4). Water distilled from the leaves, which may be advantageously used with stimulating drinks.

(5). Aqueous extract, alcoholic extract, employed as febrifuges.

(6). Tincture, or alcoholate.

(7). A liquor, which is similar to the liquor of mastic, and a wine, which is a tonic and febrifuge.

(8). Cigars and cigarettes.

Dr. Gimbert has studied, on himself, the effects of essence of *Eucalyptus* when taken into the system. He took various doses of from 10 to 20 drops. He found it had a soothing effect. It diminishes the vascular tension, and the sense of comfort arising from it induces to sleep. A very strong dose produces a temporary excitement, headache, and slight fatigue.

A. B. M.

ASSAY OF PYRITES FOR GOLD.

By J. M. MERRICK, S.B.

THE following described method has been employed by myself for more than a year, and found to work well enough to merit description.

One pound, or even 18 ounces (avoirdupois), of fine marble-dust is mixed with 8 ounces of finely-pulverised and sifted pyrites; the whole then re-sifted and put into a Hessian crucible, which should be about one-third filled by the mixture. The crucible is set as usual on a fire-brick, and a fire of hard coal is made around it, the coals being heaped up to within an inch of the top. The crucible is covered with a piece of brick or a piece of sheet-iron. During the first half hour the contents should be stirred once or twice. As the fire grows brisker the carbonic acid evolved keeps the contents of the crucible in brisk ebullition, and the mixture should be stirred well every 5 or 10 minutes. On stirring during this time, the iron rod used seems to meet with but little resistance from the light mass, but at the end of about 1½ hours the evolution of gas suddenly ceases, the red-hot mass becomes heavy, sinks, and requires considerable force to

keep it stirred. It must be stirred well and vigorously, however, for about ¼ an hour, not leaving it unstirred for more than a minute, otherwise the mass will fuse or cake, and the assay will be almost inevitably ruined.

When a sample taken out in an iron spoon gives off no smell of sulphur, the entire contents of the crucible must be turned into a stoneware pot or a wooden bucket half-filled with water, and well stirred. When the powder—which should be uniform and free from lumps or fused pieces—has settled, the water must be poured off, the wet mass allowed to drain, and then transferred to a large earthen bowl or porcelain mortar. Here it is to be amalgamated with about 2 ounces of mercury, to which a little bit of sodium amalgam has been added. The amalgamation, as well as the stirring in the fire, is a tedious process, and one which I prefer to do by proxy. It does not consist in merely grinding with a pestle the mercury in among the particles of the roasted ore, but this ore itself must be ground in contact with the mercury, until the particles are so fine that they will float suspended in water for several seconds. At the end of—say—10 minutes thorough grinding, the contents of the bowl are to be brought into one mass in the bottom of the vessel, the bowl then sunk in a tub of water, and the contents “washed down,”—an operation not easily described, but familiar enough to every old Californian. It consists essentially in shaking the bowl half-full of ore and water in such a way that the mercury, gold particles, and unground ore sink to the bottom, while the light and finely-ground ore is floated off into the tub. The ore remaining is re-ground and re-washed, and these processes are repeated till nothing but the mercury remains in the bottom of the bowl or mortar. This mercury is then dried with filter-paper, and heated in a porcelain capsule over a Bunsen flame, very gently, until it is sublimed and the gold remains behind. The film of gold may then be scraped up and melted, with a little sodic borate and potassic nitrate, in the very smallest-sized Hessian crucible, either with the foot blowpipe or in a charcoal furnace, by which means a round, clean button of gold, suitable for weighing, will be obtained.

This method—which I have subjected to a most thorough trial, my experiments having been made almost daily for 3½ months—has its disadvantages and its counterbalancing merits. On the one hand, it must be admitted to be tedious, laborious, and to a considerable degree uncertain. Some analysts fail with it altogether, while none who have tried it, so far as I know, get closely agreeing results.

But on the other side, it is certain that this method will indicate the presence of gold, and will bring out the gold in a weighable form from pyritic ores, where the assay by smelting will not show a remote trace of the precious metal; and that where the fire assay shows a certain percentage this will invariably bring out a larger amount. I have obtained large returns by this amalgamation method from iron pyritic ores, which have been repeatedly assayed in the ordinary way, by chemists of great eminence, with uniformly negative results.

It may be added, that while on this side of the water the existence of gold in any workable amount in iron pyrites is strenuously denied by the ablest assayers, the Wicklow pyrites are worked for gold and silver, as by-products to be sure, but in quantities sufficient to pay.

That no gold has been discovered by many assayers in pyritic ores, which have yielded me large results, I refer to the volatility of gold in the presence of sulphur. I imagine that the gold is roasted off in the very first step of the ordinary process. See Crookes and Röhrig's “Metallurgy,” “Gold,” pp. 629–630, and the authorities there quoted.

I have had no opportunity to put this method in practice on a large scale, and I hardly know what kind of stirring apparatus could be devised; but I have seen 20-lb. lots of ore thus roasted and stirred by hand-power, with satisfactory results.—*American Chemist*.

THE ANALYSIS OF WATERS IN INDIA.*

By EDWARD NICHOLSON, F.C.S.,
Assistant Surgeon R.A., Analyst of Waters, Mysore, Northern and
Ceded Districts.

The Fallacy of the New Bengal Method.

SINCE I last wrote on this subject, a new scheme of water analysis has appeared, in supersession of the Bengal and Madras schemes. This new scheme was compiled by Dr. Macnamara, Chemical Examiner to the Bengal Government, he having been charged, at his own request, with the production of a scheme for general use in India. A uniform scheme was desirable, even if only for the reason that the Bengal and Madras schemes differed essentially; for instance, the Bengal analysts (Dr. Macnamara's first scheme) were required to give chloride of sodium, sulphate of soda, and carbonate of soda as the three "soluble" salts existing in waters, whilst the Madras form (Dr. King's) ordered calcium sulphate, magnesium sulphate, and sodium (as sulphate) to be the three "soluble" salts. Both schemes, however, agreed in three being the number of the "soluble" salts that should be present in waters; *Numero deus impare gaudet*.

The new scheme has judiciously abandoned this artificial method of statement, and has adopted to a great extent the principle of the natural statement I mentioned in my last paper on this subject. It will be remembered that I advised strict adherence to the principle of stating the actual radical substances found in the water, without reference to the processes by which the results were obtained, and relegating to the column of remarks any empirical formula or statement of the combinations in which the radicals were supposed to exist. I showed that, by doing so, uniformity and economy of tabular space was secured, whilst no element of inaccuracy was introduced; processes could be left to the individual skill of analysts, and, if necessary, improvements could be introduced without interference with the form of statement. The whole information could be given in twenty columns.

In the scheme now ordered for adoption, this principle of natural statement has unfortunately been spoiled in practice, as the statement of the quantitative analysis has been mixed up with one (or rather two) of qualitative analysis, besides, of course, the soap test. The resulting forty-six items of information are divided into three portions; the first of these is for use in ordinary cases, and in it only two of the substances found in water (chlorine and sulphuric acid) will be stated, the rest of the report being occupied by the recital of a prolix and inaccurate qualitative examination. The remaining items of the quantitative analysis are reserved (facultatively) for extraordinary occasions; which is to some extent fortunate, as the performance of the analysis *in extenso* would occupy at least a fortnight in a well appointed laboratory; how long it would take when the analyst is working "in such accommodation as a dāk bungalow or spare barrack-room can furnish"† I will not undertake to say.

The following is the detail of the "chemical analysis." I have divided it into three columns, according to the division allowed in the scheme.

I. The part of the examination to be made in all cases.

II. The additional examination to be added under the following conditions:—(1) In the case of any exceptionally important water sources; (2) when the foregoing examination leaves any doubt as to the character of a water; (3) in the case of two water sources of any station, and of a larger number if many water sources have to be examined in any station; (4) in other cases which the Chemical Examiner at that Presidency thinks proper.

III. The further examination to be made at the dis-

cretion of the analyst or at the request of the Chemical Examiner of the Presidency.

I.

II.

III.

Qualitative Analysis.

(a). Of unconcentrated water.

1. Reaction.
2. Free carbonic acid.
3. Sulphuric acid.
4. Nitric acid.
5. Nitrous acid.
6. Chlorine.
7. Sulphuretted hydrogen.
8. Lime.
9. Iron—ferrous or ferric salt.
10. Lead, or other heavy metals.
11. Ammonia.

(b). Of water concentrated to one quarter of its original bulk.

1. Reaction.
2. Nitric acid.
3. Phosphoric acid.
4. Silicic acid.
5. Iron—ferrous or ferric salt.
6. Magnesia.

Quantitative Analysis.

A. Of suspended matter.

1. Total amount per litre.
2. Combustible matter per litre.

B. Of dissolved constituents of the water.

(a). Hardness.

1. Total.
2. Removable.
3. Permanent.

(b). General Analysis.

1. Total solids per litre.
2. Effects of ignition.

10. Chlorine.
11. Sulphuric acid.

3. Lime.
6. Magnesia.

13. Nitric acid.
14. Nitrous acid.

17. Ammonia, free, and of salts.
18. Albumenoid ammonia.

19. Oxygen removed by readily oxidisable matters.
20. Oxygen removed by oxidisable matters of water heated to 66° C.

(c). Measurement of gaseous constituents.

1. Of nitrogen (corrected for 0° C.) from 1 litre.
2. Of oxygen.
3. Of carbonic acid.
4. Oxygen and nitrogen taken at 760, state proportion of oxygen.

The scheme does not merely give a form of statement for physical and chemical examination; it retains the principle of enforcing certain processes for the determination of the items in the above form, a principle open to objection even if the processes are sound, but most injudicious when, as in the present case, any one of chemical experience can see that the processes are more often bad

* Communicated by the Author.

† The circumstances in view of which this scheme is stated to have been specially devised.

than good. If the analysts are competent for the delicate analytical work involved in measurements of gases, &c., there is no need to lay down rules for them to go by; an analyst of this experience would resent such unnecessary interference, just as the executive medical officer would resent any orders as to the treatment he should adopt in his hospital. If the analysts require to be taught their work, it would be better to place in their hands some respectable manual of analysis, and confine the scheme to an elementary hygienic examination until they shall have learnt by experience.

The processes laid down in this scheme might be useful if they were ordinarily sound, but they unfortunately bear evident traces of being derived, some from books of reference, others neither from books nor from practical experience. It may seem that I am using hard words, but it is no longer time, at the third bad-scheme, to deal gently with such grave offences against science.

Taking the second item in the qualitative analysis, I find the following process laid down for the guidance of the analyst.

"Free Carbonic Acid.—Pour a little of the water into about 5 c.c. of lime-water contained in a test-tube. If free carbonic acid is present, the precipitate of carbonate of calcium which first forms will re-dissolve on the addition of a large quantity of water."

I thereupon take a rather large-sized test-tube (holding about 30 c.c.). I pour in 5 c.c. of lime-water, and add a little (say 10 c.c.) of the water to be examined. A white precipitate appears, which increases on the addition of more water; the test-tube being full, I continue the experiment in a large beaker; I go on adding the water until I have added half a litre, yet the precipitate does not re-dissolve; by the time I have added a litre the precipitate becomes less perceptible in the large bulk of water, but it has certainly not re-dissolved. Water after water gives the same result. Even a water to which I add 10 per cent of fresh soda-water (sufficient to make it taste distinctly of carbonic acid) fails to produce, in the test-tube, the promised reaction.

The reason is obvious. The 5 c.c. of lime-water contain about 0.50 centigramme of lime (CaO); this quantity requires 0.89 centigramme of carbonate of lime, held in solution as bicarbonate, to precipitate it entirely, a reaction which must be accomplished before free carbonic acid can have any re-solvent effect on the precipitated carbonate of lime. Now a water of ordinary calcareous type containing 8.9 centigrammes per litre (6.2 grs. per gallon) would have to be added to the amount of 100 c.c. before the precipitation was complete; and it would require a water to contain no less than 89 centigrammes per litre (62 grs. per gallon) of carbonate of lime for 'a little of the water,' say 10 c.c., to complete the precipitation of the lime contained in 5 c.c. of lime-water. I can find no instance of a potable water containing an amount of carbonate of lime even approaching to this. So we find that a large-sized test-tube will be full long before any free carbonic acid has the slightest chance of re-dissolving the precipitate. When the precipitation is complete, it is doubtful whether it would be re-dissolved by the small amount of free carbonic acid that could be found in a potable water. The author of the scheme has evidently not very clear notions as to what is meant by free carbonic acid; what is often considered as such is not free, being the unstable carbonic acid holding up the carbonate of lime; any excess beyond that necessary for this purpose can only be present in minute quantity; and its detection would certainly not be effected by the process laid down, even were the largest sized vessels substituted for the test-tube ordered to be used.

Passing to the qualitative examination of the concentrated water, the following directions are given:—

"About 200 c.c. of the water should be evaporated to one-fourth its bulk, and then tested, as regards its reaction and the presence of nitric acid and iron in the manner already described." The concentrated water is apparently filtered;

no direct mention is made of this, but I infer it from the subsequent words: "*Magnesia*—To 10 c.c. of the filtrate," &c. Now I may here observe that the result of the concentration will be to deposit the greater part of the earthy carbonates, perhaps some silicates, and whatever phosphoric acid and iron the water contained. So the analyst on examining the concentrated water will find—(1) that the reaction is alkaline, just as it was before concentration; (2) that the nitric acid is present or absent, just as it was before concentration; (3) that the iron, if present before, has now disappeared, saving him the trouble of ascertaining its condition as a "ferrous or ferric salt." The first two results are of questionable utility, whilst the third will probably be unexpected and productive of some perplexity. The analyst having wasted his time in this manner and searched for magnesia in the filtrate (it is to be hoped that it has not gone all down in the deposit), is directed to proceed as follows:—

"The portion of concentrated water which remains must be tested for phosphoric acid. Add a slight excess of hydrochloric acid, evaporate to dryness in a platinum capsule, and ignite in order to render any silicic acid insoluble. Treat the residue with about 1 c.c. of dilute nitric acid, filter, and mix the filtrate with an equal bulk of solution of molybdate of ammonium and about half the quantity of pure strong nitric acid. If phosphoric acid is present, a yellow crystalline precipitate will form immediately or after a short time."

In the absence of any specific directions, the analyst will naturally take the rest of the filtrate after using some for magnesia, &c.; he will operate as directed on these 20 to 30 c.c. of concentrated water, and after much trouble he will invariably find nothing. Even if he disregarded the instructions and took the precipitate instead of the concentrated water, he would not be much better off; 200 c.c. of water are not nearly sufficient for the detection of the very minute quantity of phosphoric acid usually present in water, and, moreover, the molybdate of ammonia process ordered is one of the most untrustworthy known. However, the certain non-appearance of phosphoric acid in the above-indicated process will be compensated by the probable appearance of platinum; for if the water contain nitrates in at all notable quantity, evaporation with hydrochloric acid will hardly fail to attack the platinum capsule,* so that in the following note: "*Silicic acid*—The residue undissolved by nitric acid may be looked upon as silicic acid," it would perhaps be more correct to read *platinum* for *silicic acid*.

(To be continued.)

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.†

By Dr. F. CRACE CALVERT, F.R.S.

(Continued from p. 55).

Blue Colouring Substances.—*Indigo, Orchil, Cudbear, Litmus, Prussian Blue, and Ultramarine.*

Indigo.—This most valuable dyeing substance was used as a dye-stuff in India and Egypt long before the Christian era, and the Romans were acquainted with it, although they only used it as a pigment, not knowing how to render it soluble, and so available for dyeing. It is only since the sixteenth century, or from the time of the discovery of the passage to India round the Cape of Good Hope, that it has become generally known in Europe; and its employment as a dye was greatly retarded by the opposition it met with from the large vested interests of the woad cultivators, who induced

* If the nitrous waters of India are thus treated, this accident will occur. I have had a platinum capsule attacked to the extent of half a grain.

† The Cantor Lectures, delivered before the Society of Arts. Revised and communicated by the Author.

the English, French, and German governments to promulgate several enactments against its use. So severe were some of them, that Henry IV. of France issued an edict, condemning to death any one who used that pernicious drug called the "devil's food." It is only since the year 1737 that the French dyers have had the right of using indigo without restriction.

Indigo exists in several varieties of plants, among which may be mentioned the *Polygonum tinctorium* and the *Isatis tinctoria*, or woad; but, as in the case of nearly all the dye-stuffs already spoken of, it is found most abundantly in plants of the leguminous order. It is extracted commercially from the genus *Indigofera*, varieties of which are cultivated in India, Java, China, and in some of the South American States.

To extract the indigo which the plant contains, it is mowed when in full flower, made into bundles, and carried into large vats containing water. Fermentation ensues, which is allowed to proceed for eight or nine hours, when the liquor, which was yellow at the beginning of the operation, assumes a dark green colour, forming a blue scum on the surface. This liquor is then run off into shallow vats, where it is violently agitated with sticks, stirred by men or women or with a dasher, which produces the same result, the conversion of the white soluble indigo into blue insoluble indigo. A little lime-water is now added, and the whole allowed to rest. The blue indigo thus deposited is boiled with water, when a scum, composed of vegetable and animal matters, comes to the surface, and is removed. The blue paste is thrown on a filter, pressed, and placed in wooden frames, which are divided into small squares, where the indigo is allowed to dry first in the sun and afterwards in the shade. The quality of the indigo produced depends mainly on the care bestowed on its manufacture.

Until 1855 we had no correct ideas as to the state in which the indigo existed in the *Indigofera* plants, nor of the changes which it underwent during the process of extraction. It had been stated by M. Chevreul, many years before, that white indigo was oxidised into blue. But in the above year, and subsequently, in 1857 and 1865, Dr. Schunck published a series of papers, in which he described the true nature of the chemical changes which take place in the manufacture of indigo. He operated on the *Isatis tinctoria*, or woad, which contains the same colour-giving principle as the *Indigofera*, and is the only plant yielding indigo that grows freely in this country.

By these researches, he demonstrated that indigo existed in the plants, combined with a sugar, forming a glucoside, to which he gave the name *indican*; this compound, under the influence of fermentation in the manufacturing process, was unfolded into indigo and sugar. By treating the dried woad with ether or alcohol, Dr. Schunck obtained indican, and, among other processes for its extraction, gives the following simple one. He treats the pounded dried woad leaves with ether in a displacement apparatus, and distils off the greater part of the ether. The remaining green liquor is then evaporated at a moderate temperature, a little cold water added to the syrupy residue, and the insoluble chlorophyll and other matters separated by filtration. The yellow liquid thus obtained is evaporated, either spontaneously or *in vacuo*.

Indican is a yellow, transparent, glutinous solid. As may be seen from the above, it is soluble in alcohol, ether, and water. When boiled with caustic alkalies, it evolves ammonia, but its most remarkable and interesting property is that of yielding indigo blue when treated with strong acids. If sulphuric or muriatic acid be added to its water solution, no change whatever is perceptible for some time. But on heating to near the boiling point, the solution immediately becomes sky-blue. On boiling for a short time, the solution becomes opalescent. On continuing to boil, it acquires a purple colour; and then, provided the solution is tolerably con-

centrated, a copious deposit of dark purple flocks is formed. These are collected on a filter, and washed with water. By treating the washed flocks with alcohol, Dr. Schunck obtained pure indigotine, and a reddish blue substance was dissolved, called by Berzelius indigo-red, and by Schunck indirubine, which may be considered as a product of the decomposition of indican.

The colour-giving principle of the plant may be considered, like those of the dye-woods, as a glucoside, yielding by its decomposition a colourless principle, which is afterwards converted into a colour. Dr. Schunck explains by the following formula the decomposition of indican into indigo:—

In 1864 he published a most valuable paper, throwing much light on the manufacture of indigo, and the management of what is called a woad vat. In it he gives the chemical actions which take place, and explains why, if the indigo manufacturer does not take the greatest care in conducting the process of fermentation, to extract the indigo from the plant, he will either get an inferior quality of indigo, or a great decrease in the yield of the product, or even in some cases entirely lose the colouring matter. He shows that these results take place when the fermentation in the vats is allowed to be either too rapid or too prolonged, in which cases not only is indican decomposed, but the *indiglucine*, or sugar, is converted into alcohol and acetic acid; and he shows that the indigo combines with this alcohol and acetic acid, yielding a compound which does not permit the indigo it contains to be oxidised on exposure to the air. This explains the loss of indigo in its manufacture. Dr. Schunck represents the change by the following formulæ:—

He produced this compound more easily by treating pure indigo blue with alcohol, to which was added an alkaline solution of protoxide of tin, until the indigo was dissolved, acetate of soda was then added, and the whole digested at a moderate temperature. The indigo blue after some time ceased to be deposited on exposure to air, having entirely disappeared, having been converted into the new compound.

Pure indigo, or indigotine, can be prepared from indican by the process already described, or by reducing indigo to powder, placing it in a small dish on which is a cover, and applying a heat of about 300° or 400° Fahr., when beautiful prismatic needles of indigotine are sublimed, which are removed mechanically. It is insoluble in water, alcohol, or ether, or in weak acids, or alkalies, but is slightly soluble in creosote, carbolic acid, and anhydrous acetic acid, to which a very small quantity of sulphuric acid has been added. From this latter solution, the indigotine may be precipitated by the addition of water. It is the only solution of blue indigo that can be applied directly on a fabric.

Indigotine, when heated, gives off beautiful violet vapours, having a characteristic odour. Under the action of oxidising agents, such as nitric acid, it yields three distinct products, *isatin*, $\text{C}_8\text{H}_5\text{N}_2\text{O}_2$; *indigotic or nitrosalylic acid* $\text{C}_7\text{H}_3(\text{NO}_2)\text{O}_3$, and *picric acid*, $\text{C}_6\text{H}_3(\text{NO}_2)_3\text{O}$. The first is formed by simple oxidation, whilst in the second and third, part of the carbon is oxidised, and hyponitric acid is substituted for part of the hydrogen. These chemical reactions lead me to call your attention to some very interesting scientific deductions, showing indigo to bear a very close relation to aniline and carbolic acid, both products derived from coal-tar. If indigotine is heated with potash in a small retort, aniline is produced, and distils over. When indigo is heated for some time with caustic potash solution of specific gravity 1.35, it yields anthranilic acid, which may be considered as a

phenyle-carbamic acid. Anthranilic acid, again, being heated to 570° F., gives salicylic acid, which may be considered as a compound of carbonic with carbolic acid. Lastly, indigotine, like carbolic acid, yields on treatment with excess of nitric acid, picric or trinitrophenic acid.

These facts have produced on the minds of chemists a conviction that indigotine will one day be artificially prepared from carbolic acid, and recently MM. Emmerling and Engler have accomplished the scientific artificial production of indigotine from a compound acetone, discovered in 1857 by M. Friedel, to which these gentlemen have given the name of acetophenone. Their process consists in acting on this compound with fuming nitric acid, when two nitro-compounds are produced, one crystalline, the other syrupy. To the latter, after its evaporation to the state of a resinous mass, they add ten parts of reduced zinc and one part of soda-lime. The mixture is heated in small tubes, when a little water evaporates and a dark-coloured substance sublimes, which contains indigotine in small quantities. This result is certainly a triumph of scientific chemistry, and brings us another stage nearer the commercial artificial production of a most valuable dye.

A great variety of substances, by adding one equivalent of hydrogen, convert blue indigo into white indigo, which is a colourless substance, without taste or odour, insoluble in water, but soluble in alcohol and ether, and in solutions of the alkalies and alkaline earths. On this point I may observe that, many years ago, I devised a process, by which many pounds worth of indigo were recovered from the refuse bottoms of the blue dip vats, the preparation of which I shall explain further on. I found that indigo was susceptible of forming insoluble compounds with the lime and protoxide of iron. White indigo dissolves freely in strong sulphuric acid, giving a dark purple blue liquor.

Many substances are employed commercially to convert blue indigo into the white indigo, soluble in alkalies. Thus, I may mention lime and protoxide of iron, caustic alkali and protoxide of tin, or sulphuret of tin or arsenic, and zinc and caustic alkali; also organic substances, such as grape sugar and bran, which enter easily into fermentation. The following formulæ shows the difference of composition of the two indigos:—

I shall now have the pleasure of proceeding to describe some of the methods employed by chemists to determine the relative commercial value of samples of this expensive dye. The best qualities of indigo from Bengal, Java, and Guatemala are light, have a uniform texture, and a fine coppery hue, which is increased by friction. The following analysis, made by M. Chevreul, shows the composition of a fair sample of commercial indigo:—

Indigotine	45
Matters soluble in alcohol	30
Matters soluble in ether	12
Resin soluble in hydrochloric acid ..	6
Mineral matters	7

100

Commercial indigos are often adulterated with mineral matters of various kinds. This fraud is easily detected by calcining a known weight of the sample, which ought not to leave a residue of more than 10 per cent. The most common adulteration, however, is the addition of starch. This can be detected by boiling some of the pulverised indigo with a weak solution of hydrochloric acid. The insoluble starch is thus converted into soluble dextrine, which yields a beautiful purple colour with iodine.

There are several processes employed to determine the amount of indigotine in commercial indigos. I shall

here only give the outline of three. The first consists in dissolving 1 grm. of the dry pulverised indigo in 12 grms. of concentrated sulphuric acid, and heating the whole at a temperature not exceeding 120° F., when the indigo combines with the sulphuric acid, and becomes perfectly soluble in water. It is then diluted with water, so that the whole occupies one litre. The operation is repeated with 1 grm. of pure indigotine, which serves as a standard of comparison. A solution of bleaching-powder or bichromate of potash—the first proposed by M. Chevreul, the latter by Dr. Penny—is prepared of such a strength that 100 volumes of the solution will completely destroy the whole of the colour produced by the grm. of indigotine. Part of the same liquor is then applied to the solution of the commercial indigo, and the number of volumes required to destroy the colour represents the percentage of indigo. Thus, if 60 divisions are required, it is assumed that there is 60 per cent, if 70 divisions 70 per cent. This method of estimating the indigotine is not to be relied on, as it always gives a much higher percentage of colour-giving principle than exists in the indigo, owing to the hypochlorous acid of the bleaching-powder and the chromic acid of the bichromate not only decomposing the indigotine, but acting on several colouring matters which are included in the portion soluble in alcohol in M. Chevreul's analysis.

The second process gives better results; it is due to Professor Fritzsche, and consists in introducing one part of indigo, finely pulverised, and one part of grape sugar, into 48 or 50 parts of boiling alcohol, to which is added 2 parts of a concentrated solution of caustic soda. The whole is put into a bottle exactly large enough to hold it and left to cool. By exposing the colourless liquid to the atmosphere, the reduced indigo which is in solution absorbs oxygen, and the indigotine is precipitated under the form of beautiful prismatic crystals.

The third process, devised by myself, I have found to give satisfactory results. It consists in introducing into a flask 1 part of finely pulverised indigo, 2 parts of green copperas, and 200 parts of water containing 10 per cent of caustic soda. The whole is kept at the boil for a short time, and allowed to cool. The clear liquor is exposed in shallow vessels to the atmosphere, when the soluble indigo is oxidised, and precipitates as pure indigotine. The residue in the flask is submitted to the treatment three times. The whole of the indigotine thus obtained is collected on a filter, dried, and weighed.

A commercial process, founded on the above method, is carried on by Messrs. Haas and Co., who sell indigo so purified under the name of refined indigo. An inferior quality is also prepared by heating indigo, at a moderate temperature, with weak muriatic acid, which dissolves lime and other mineral matters, as well as any starch it may contain; it is slightly washed and boiled with weak caustic soda, to dissolve the chlorophyl and other resinous impurities.

(To be continued.)

LABORATORY NOTES.

NEW APPARATUS FOR GENERATING H₂S, CO₂, AND H.

New forms and new modifications of apparatus are constantly being proposed and described for the convenient generation of H₂S, CO₂, and H in laboratory work. Many of these are somewhat complicated and expensive, more or less difficult to fill, and liable to breakage; as, for instance, the much-used apparatus of Kipp. I think the following simple application of an old principle will be found worthy of trial. The apparatus is cheap and easily made by anybody in a very short time, is easy to move about and to fill, and possesses every advantage of

more complicated ones, as regards being always ready and easy of regulation.

is a little over two-thirds full of the dilute acid. According as the stop-cock is opened, a stream of gas of any required amount is given off, and on closing the cock the acid is all driven into the jar. It is evident that the tube A B must not fit air-tight into the stopper of the jar. The best way of arranging is, after boring the hole in the cork for the tube A B, to cut a little channel with the triangular file, just sufficient to allow of the rise and fall of the liquid in the jar.

A jar about 10 inches high, and proportionately wide, with a tube of 1 to 1½ inches bore, gives a very suitable apparatus for ordinary use. By using a very large jar, or a large cylinder, and larger and much longer tube, a constant stream may be had for many days.

W. M. HUTCHINGS.

NOTICES OF BOOKS.

Experimental Chemistry, founded on the Work of Dr. Julius Adolph Stöckhardt. A Handbook for the Study of the Science by Simple Experiments. By C. W. HEATON, F.C.S., Professor of Chemistry in the Medical School of Charing Cross Hospital. London: Bell and Daldy. 1872.

THERE are two methods of studying chemistry, one by reading works on chemistry, but only one by which the student can become a chemist, by acquiring facts experimentally. Many handbooks are written merely as exponents of chemical theory, and leave experimental illustration to the care of the professor or teacher. But Mr. Heaton has adopted the true method of imparting a knowledge of chemistry by studying the science by simple experiments. These experiments, however, are not unassisted by theory in its proper place, that of a classification of facts from which laws may be deduced; and theoretical consideration is even extended to include the principles of correlate science with the most happy result. The success of Mr. Heaton's method of teaching

is well known, and we cannot do better than refer students to his work. Organic and inorganic chemistry—both are dealt with, every experiment being illustrated with a woodcut showing the disposition of the apparatus employed. The various kinds of chemical formulae also are admirably explained. Indeed, this may be said to be a perfect manual of elementary chemistry.

The Chemical History and Progress of Aniline Black. By JOHN LIGHTFOOT, Chemist. Published by the Author at Lower House, Burnley, Lancashire. 1871.

MR. LIGHTFOOT states the object of his pamphlet to be to give to chemists and others connected with dyeing and calico printing the history and progress of aniline black during the past ten years, as well as some curious experiments made with the purpose of determining many debated points of the processes of preparation. Mr. Lightfoot is the inventor and the first to introduce aniline black upon calico, so that the work has importance of the highest order. Inclusive mention is made of many important experiments with aniline black, including the results of the treatment of the prepared cloth with all the metals, scarce, noble, and common, a matter of enormous expenditure. There are many minor experiments of great interest, among which is the following:—An experimental normal colour was printed upon a piece of calico with a wood block, and whilst still wet a shilling and a sovereign, previously cleaned in nitric acid and water, were placed upon the cloth for fifteen minutes; the calico was aged twelve hours and washed, no trace being shown of the contact of the coins. The same coins were then placed in a bag with copper coins, and slightly shaken up with them. Applied then in the same way to the calico, and under the same conditions, the sovereign gave a dark slate, and the shilling an all but black colour. The mere rolling of a copper coin over the wetted calico is sufficient to induce the formation of the black.

We would wish to make a more lengthy extract, but in fairness to the author, who has been at such great expense with the experiments, we must refer to the pamphlet itself for results. To all who have much to do with calico printing the contents will be highly valuable.

CORRESPONDENCE.

WANKLYN AND CHAPMAN'S WATER ANALYSIS.

To the Editor of the Chemical News.

SIR,—Now that the "ammonia process" of Messrs. Wanklyn and Chapman is being generally accepted, it is proper that every phase of the question should be examined. May I therefore, through your columns, call the attention of the authors to two apparently conflicting statements in this little manual of "Water Analysis."

In the first edition, page 48, it is stated that, in distilling water, towards the end of the operation ammonia appears in the distillate, and that this latter portion must be rejected. Now, in estimating the free ammonia in water, it is recommended to distil only about 100 or 200 c.c., and then to add permanganate and proceed with the determination of the albumenoid, NH_3 . What becomes of that portion of the ammonia which would be found in the receiver if the distillation had been carried nearly to dryness? Is this amount carried over with the albumenoid NH_3 , or is this residual ammonia, as I may call it, merely the result of the decomposition of the albumenoid matters in the water? Have the authors ever made any experiments to determine the amount of NH_3 which will pass over at the conclusion of the distilla-

tion of ordinary water? I think it but right to call attention to this matter, as I believe that the ammonia method is destined to supersede all others, and that Messrs. Wanklyn and Chapman deserve the thanks of chemists for the ability and perseverance they have displayed. Hoping to gather from your readers some information upon the subject,—I am, &c.,

HENRY LEFFMAN, M.D.

417, Walnut Street, Philadelphia,
July 20, 1872.

ON THE PRESENCE OF ARSENIC IN COLOURED PAPERS.

To the Editor of the Chemical News.

SIR,—The danger arising from the use of arsenical colours in the manufacture of ornaments or toys cannot be over estimated.

The many illustrations given by Dr. Draper show how very common is the use of arsenical greens, on account of their superior brilliancy and stability when exposed to light.

I have found the poison also in a sample of "magenta" tissue paper, which had been used for Christmas decorations. The friend who brought it to me noticed the alliaceous odour peculiar to arsenic when the paper was burnt. It was indeed so strong as to be unmistakable. I could easily detect arsenic by all the ordinary tests. Unfortunately, the sample was thrown aside without any quantitative estimation having been made. The paper must have been coloured with a very crude "magenta." I have not been able to extend the investigation to other articles of the same colour; but I think that the evil arising from the inhalation of minute quantities of arsenic being so great, its use in colours should be entirely prohibited.—I am, &c.,

G. J. WARNER.

Ardwick Bridge Chemical Works,
Manchester, July 29, 1872.

MISCELLANEOUS.

Chemical Appointments.—Dr. W. A. Tilden has been appointed Lecturer on Chemistry at Clifton College; and Mr. Frank Clowes, B.Sc. Lond., F.C.S., has been appointed Science Master at Queenwood College, Hants.

The British Association.—The Brighton meeting will commence on Wednesday, August 14, and continue till Thursday, August 22. On Thursday evening, the 15th, and on Tuesday evening, the 20th, *soirées* will be held. The entire northern block of the Pavilion property is allotted to these—namely, the Dome Assembly Room, the adjoining large building used in the days of the Regent as the Royal riding school, but now converted into a corn-exchange, and the recently-built free library and museum. The exhibition of pictures, articles of vertu, philosophical instruments, and objects of artistic and scientific interest will be very large and varied. The Brighton Natural History Society are arranging a complete flora of the south coast, both living and dried specimens; also a microscopical display, to which the most eminent London makers and the leading metropolitan societies will contribute. It is anticipated that about 400 microscopes will be in use during each *soirée*. On Friday evening, the 16th, and Monday evening, the 19th, lectures will be delivered by leading scientific men. An announcement has been made by the *Athenæum* that whatever information is received from Dr. Livingstone will be communicated at this Brighton meeting of the association. The Town-hall room, designated for the Geographical Section, will hold some 900 people; but it has been suggested that the Livingstone communications should be read in the Dome Assembly-room, which will seat from 2500 to 3000 persons. Four half-day excursions

are arranged for Saturday, August 17, and five for Thursday, August 22. In connection with these several county noblemen and gentlemen will display liberal hospitality. The new Brighton Aquarium will be opened and stocked for the meeting of the association. Many invitations have been sent through the Mayor of Brighton, Mr. Cordy Burrows, to Continental and American savans, who will attend the meeting as the guests of the municipality. Numerous acceptances have already been received. Working men delegates are also invited from London and the chief centres of industry and manufactures, and a special lecture for working men will be delivered by Mr. W. Spottiswoode, F.R.S. As to the railway arrangements, return tickets will be issued by the Brighton Company to members of the association available from the 12th of August, or any following day, to return by any train and on any day to the 26th of August. Special fortnightly or monthly tickets, at reduced rates, will also be issued to members of the association, available to travel by any train between London and Brighton for the term. The railway company will also allow these fortnightly and monthly tickets to be issued to members of other scientific bodies in London on production of proof of membership. Applications for association tickets and local information should be addressed to the Rev. J. Beck, Secretary of the Local Executive Committee, at the Royal Pavilion, Brighton. The following are the officers elected:—President Elect—Dr. W. B. Carpenter, F.R.S. Vice-Presidents Elect—The Earl of Chichester; the Duke of Norfolk; the Duke of Richmond; the Duke of Devonshire, F.R.S.; Sir John Lubbock, Bart., M.P., F.R.S.; Dr. Sharpey, Sec. R.S.; Mr. Joseph Prestwich, F.R.S., Pres. G. S.—Section A. Mathematical and Physical Science. President—Warren De La Rue, F.R.S. Vice-Presidents—J. Norman Lockyer, F.R.S.; Lord Rosse, F.R.S.; Prof. H. J. Stephen Smith, F.R.S. Secretaries—Prof. W. K. Clifford; R. A. Proctor; A. C. Ranyard. Section B. Chemical Science. President—Dr. J. Hall Gladstone, F.R.S. Vice-Presidents—F. A. Abel, F.R.S.; Professor Williamson, F.R.S. Secretaries—Dr. Mills; W. Chandler Roberts; Dr. W. J. Russell, F.R.S.; T. Wood. Section C. Geology. President—R. A. C. Godwin-Austen, F.R.S. Vice-Presidents—Thomas Davidson, F.R.S.; Prof. P. M. Duncan, F.R.S.; Rev. T. Wiltshire. Secretaries—Henry Woodward; Louis C. Miall; G. Scott; William Topley. Section D. Biology. President—Sir John Lubbock, Bart., M.P., F.R.S. Vice-Presidents—John Ball, F.R.S.; Dr. Beedoe; Prof. Flower, F.R.S.; Col. A. Lane Fox; J. Gwyn Jeffreys, F.R.S.; Dr. Burdon Sanderson, F.R.S. Department of Zoology and Botany. Sir John Lubbock, Bart., M.P., will preside. Secretaries—Prof. Thimelton Dyer; H. T. Stainton, F.R.S. Department of Anatomy and Physiology. Dr. Burdon Sanderson, F.R.S., will preside. Secretaries—Dr. Gamgee, F.R.S.; E. Ray Lankester; Dr. Rutherford; Dr. Pye Smith. Department of Anthropology. Col. A. Fox Lane will preside. Secretaries—Dr. Charnock; F. W. Rudler; J. H. Lamprey. Section E. Geography. President—Francis Galton, F.R.S. Vice-Presidents—Clements R. Markham; Major-General Sir Henry Rawlinson, Bart., F.R.S., Pres. R.G.S.; Major-General Strachey, F.R.S. Secretaries—H. W. Bates; A. Keith Johnston; Rev. J. Newton; J. H. Thomas. Section F. Economic Science and Statistics. President—Prof. Henry Fawcett, M.P. Vice-Presidents—R. Dudley Baxter; William Newmarch, F.R.S. Secretaries—J. G. Fitch; Edmund Macrory; Barclay Phillips. Section G. Mechanical Science. President—Frederick J. Bramwell, C.E. Vice-Presidents—John Hawkshaw, F.R.S.; C. W. Merrifield, F.R.S.; Charles B. Vignoles, F.R.S. Secretaries—H. Bauerman; J. Gamble.

Royal College of Science for Ireland.—The following is a copy of the examination paper used by Professor Galloway for the senior students in Practical Chemistry, on June 8th, 1872. **General Instructions.**—The same

value is attached to each determination. Six hours are allowed for the analyses. *Assaying—For the Students in Mining.*—1. Determine the amount of copper in the sample of mine-water given you; each stroke of the pump delivers 33 gallons of this water, there are four strokes a minute, and the pumping is continued night and day. Calculate from your assay how much copper precipitate ought to be produced in twelve months, the copper precipitate containing 56 per cent of copper. 2. Determine by *wet* assay the amount of zinc in the sample of calamine given you, and give the quantity in 1 ton of the ore. 3. Determine by *dry* assay the quantity of lead in the sample of galena given you, and give the quantity in 1 ton of the ore. 4. Determine by *wet* assay the quantity of iron in the sample of hæmatite given you, and state the quantity in 100 parts. *Quantitative Analysis—For the Students in Manufactures.*—1. Estimate the amount of chlorine in the sample of chloride of lime given you, and calculate the quantity in French as well as in English degrees. 2. Determine the amount of free acid and water, and also the amount of chloride of sodium in the sample of salt-cake given you, and give the percentage results. 3. Determine the amount of nitrate of soda in the sample of crude soda-nitrate given you, and state the amount in 100 parts. 4. Determine the amount of copper in the sample of burnt pyrites given you, and state the amount in 20 tons of the burnt ore. *For the Students in Agriculture.*—The percentage amounts of the substances to be determined to be given in each case. 1. Determine the amount of non-volatile matter in the sample of guano given you. 2. Determine the amount of soluble phosphate in the sample of superphosphate given you. 3. Determine in the sample of crude sulphate of ammonia given you the quantity of sulphate of ammonia it contains. 4. Determine the amount of nitrate of soda in the sample of crude soda-nitrate given you.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, with therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Stances de l'Académie des Sciences, July 22, 1872.

This number contains the following original papers and memoirs relating to chemistry, &c.:—

Iron in the Blood of a Non-Vertebrate Animal.—Dr. Bous-singault.—This essay contains the record of a series of experiments made by the author with the view of estimating the iron present in the blood of the common garden-snail. The blood, obtained by opening the heart (which, however, only yields one or two drops), is a slightly opalescent fluid, and is nearly colourless; it becomes, by exposure to air, a semi-gelatinous mass; viewed by the microscope, it is found to contain elliptical globules of about the same size as those seen in the blood of cows, and exhibits an alkaline reaction; it contains, in 100 parts—Water, 96.95, and dry substance, 3.95; while the ash amounts to 0.76, and the iron (as metal) to 0.0069. The flesh of the same snails contains, in 100 parts—Water, 84.88, and dry matter, 15.12; while the ash amounts to 3.0 per cent, and the iron (as metal) to 0.00176. 100 parts of the dried snail-blood contain—Iron, 0.0177; and 100 parts of the dried flesh contain—Iron, 0.0078. The blood of oxen contains about ten times more iron than their flesh, while the white blood of the snails contains only about twice the quantity of iron contained in their flesh.

New Process for the Estimation of Ozone.—P. Thenard.—The process is based upon the oxidation of arsenious acid by ozone. A slight excess of a titrated solution of arsenious acid (dissolved in hydrochloric acid) is poured into the bottle containing the ozone, the bottle is then well shaken, and the fluid titrated with permanganate of potassa. The author has purposely tried the effects of nitric, nitrous, and hyponitric acids, and he has found that these substances do not interfere with the correctness of the reaction alluded to, neither

does peroxide of hydrogen (oxygenated water). As regards the action of permanganate of potassa upon oxygenated water, the author states that Dr. Brodie's experiments on this subject hold good at the ordinary temperature of the air (then the permanganate is discoloured by the oxygenated water, the disposable oxygen of both being evolved), but the author finds that, when the mixture of the two substances alluded to is cooled by means of a freezing mixture, the oxygen of the permanganate, which becomes discoloured, is retained in the fluid, and remains combined with it as long as the low temperature is applied to the mixture.

New Process of Preserving Food Materials by means of Acetate of Soda.—Dr. Sacc.—This process consists in treating meat and vegetables either with a strong aqueous solution of, or with dry acetate of soda. The substances are left in contact with that salt from twenty-four to forty-eight hours, and then dried. Meat may be placed in a strong solution of the salt alluded to; the brine from the meat is to be evaporated, and is to be added to it when being cooked, in order to restore to it a portion of the salts and extractive matter taken up by the acetate of soda, the preservative action of which seems to depend upon the withdrawal of water from the alimentary substances.

Constitution of Acid Salts while in Solution.—Dr. Berthelot.—Notwithstanding the high scientific merits of this paper, which contains a series of formulæ, its contents are not suited for abstraction; an observation also applicable to the following essay:—

Theory of the Explosion of Detonating Materials.—P. Champion and H. Pellet.

Preparation of Ozone by means of a New Method of Producing an Electric Current.—A. Boillot.—By means of glass tubes coated with coke powder (rendered adhesive to the glass by means of gelatine), a current of galvanic electricity is caused to pass continuously, and without producing sparks, over oxygen, which is thus slowly converted into ozone.

This number contains several important memoirs relating to physiology, meteorology, acoustics, and geology.

July 29, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

Quantity of Iron Contained in the Various Organic and Organised Constituents of the Blood.—Dr. Bous-singault.—This memoir contains the detailed account of a series of experiments made with the view to ascertain the quantity of iron (as metal) contained in the various constituents of blood. 100 parts of fibrin contain 2151 of mineral matter, and 0.0466 metallic iron. 100 parts of the blood-globules contain 1335 mineral matter, and 0.350 iron. 100 parts of albumen contain 8715 mineral matter, and 0.0863 iron. 100 parts of human blood contain 0.3 fibrin, 7.0 albumen, 12.7 globules, 10 mineral matter, and 79.0 water. 100 parts of cows' blood contain 0.4 fibrin, 7.4 albumen, 10.3 globules, 10 mineral matter, 80.7 water. The large quantity of iron met with in the blood-globules is due to the hæmatose, which, when separated from defibrinated blood, is of a deep brown colour, insoluble in pure water, but soluble in water which has been rendered slightly alkaline. 100 parts of hæmatose contain 1079 of mineral matter, wherein are 6.33 metallic iron, equal to 90.43 peroxide of iron, leaving 1707 other mineral matter. Further research exhibited the presence of lime and phosphoric acid in the ash of hæmatose, which (the ash) was found to consist, in 100 parts, of 84.12 peroxide of iron, 13.512 phosphoric acid, and 2.986 lime. 100 parts of hæmatose consist of 89.25 organic matter, 9.04 peroxide of iron, 1.45 phosphoric acid, and 0.32 lime.

Researches on the Carbon and Soluble Salts Contained in the Ovi-fak (Greenland) Meteorite.—Dr. Daubrée.—After referring to his former paper on this subject, the author gives an exhaustive account of his researches, more particularly relating to the proportions of free and combined carbon present in the meteorite referred to. The author distinguishes three different types in this mineral; the composition of each of these types is quoted as follows:—

	First Type.	Second Type.	Third Type.
Metallic iron	40.94	80.8	61.99
Combined iron	30.15	1.6	8.11
Combined carbon	3.00	2.6	3.60
Free carbon	1.64	0.3	1.10
Silicium	0.73	0.291	Not estimated.
Water	2.86	0.700	"

Chlorides of iron and calcium, soluble in alcohol, were found in the second and third types per centally as follows:—

	Second Type.		Third Type.
	Non-malleable Part.	Malleable Part.	
Chloride of calcium	0.455	0.100	0.110
Chloride of iron	0.106	0.098	0.119

As regards the salts soluble in water, the following particulars are given for 100 parts in each type:—

	First Type.	Second Type.	Third Type.
Sulphate of lime	1.288	0.053	0.047
Chloride of calcium	0.039	0.233	0.116
Chloride of iron	0.027	0.089	0.114
	1.354	0.375	0.277

Constitution of Acid Salts when in Aqueous Solution.—Dr. Berthelot.—The continuation of a monograph on this subject.

Empyreumatic Hydrocarbons from Pêchebroun (Alsace).—J. A. Le Bel.—The main gist of this paper relates to the methods em-

ployed for separating from each other two iodhydrates of amylene, one of which boils at 130°, and the other at 145°. This separation has been effected by means of hydrochloric acid at the ordinary temperature. In another portion of this memoir the author describes some experiments made with the view of converting hexylene into an isobutyl alcohol by means of sulphuric acid.

Industrial Preparation of Aniline Colours.—Ch. Girard and G. de Laire.—This paper mainly contains a refutation and correction of statements made and published by M. Lauth affecting the scientific labours of the authors, who affirm that they have not exaggerated the dangers arising from the use of arsenic acid in this branch of industry.

Study on the Gaseous Matter Evolved at Santorin (Italy) during the Volcanic Eruption of 1866.—M. Gorceix.—This memoir, elucidated by several tables exhibiting the results of experiments, is a valuable contribution to our knowledge on the subject of the gaseous matter evolved during volcanic eruptions.

Among the meteorological memoirs contained in this number, we call attention to the following:—

Fall of a Meteorite in the Commune de Lancé, Canton de Saint-Amand (Loir et Cher).—M. de Tastes.—This paper, illustrated by a map delineating the course of the meteorite, contains a detailed and well-authenticated account of the phenomena observed during the fall of this meteorite.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 236, August, 1872.

Report on the Phosphoric Acid and Phosphates Manufacture of Blanchard.—M. Barral.—This exhaustive memoir contains the account of the author's visit to the works alluded to, and already mentioned in the *CHEMICAL NEWS*, vol. xxvi., pp. 47 and 48. As an appendix to these works, M. Barral has, it appears from a brief note added to this report, established at Pantin (near Paris) a small factory for the purpose of extracting from sewage-water the ammonia it contains, by first adding to that water (heated by means of steam to a temperature of 30° to 35°) milk of lime, and next forcing a current of air through it by means of a blowing-van. The air, charged with ammonia, is made to pass through sulphuric acid, whereby sulphate of ammonia is produced. It appears that this method of eliminating the ammonia is very successful and rapid in action.

Bitumen and its Application to Public Works.—M. Homberg.—An important contribution to our knowledge on asphalt and its applications.

Contrivance for Freezing Water.—E. Carré.—The description, illustrated by a woodcut, of an ice-making machine.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, May 26, 1872.

Testing and Verification of Alcoholometers and Areometers.—M. Collardeau-Vacher.—The continuation and concluding portion of this essay, copiously elucidated by tables and algebraical formulæ.

Newly-Contrived Apparatus for Indicating the Presence of Marsh-Gas in Coal-Pits.—M. Turquan.—The description of a rather complicated apparatus intended for the protection of pitmen from the danger of explosions.

Lacto-Butyrometer.—M. Marchard.—The detailed description, illustrated by woodcuts, of an instrument intended for the purpose of testing the quality of milk and its richness in butter.

Method for Ascertaining the Heating of Portions of Machinery.—Dr. Mayer.—In order to test whether any bearings or parts of machinery become heated by friction, the author proposes to cover the parts with a thin layer of iodide of mercury, as this red-coloured salt becomes black when exposed to a temperature of about 70°.

Gazzetta Chimica Italiana, No. 5, 1872.

This number contains the following original papers and essays:—

Determination of the Molecular Weights of the Saline Substances.—Dr. E. Paterno.—This memoir contains a review of the relation existing between the electrolytical equivalents and the molecular weights of some saline bodies. The author deduces from the researches of Faraday, Matteucci, and Becquerel that the electrolytical equivalents of the salts frequently correspond to their molecular weights; and he further holds that Faraday's law bears upon the decomposition of an equal number of molecules by equally strong electric currents, and that this may be applied to the determination of the molecular weight of the salts, which then are to be formulated, as exhibited in the following instances:— CuCl_2 and CuCl_2 ; HgCl_2 and Hg_2Cl_2 ; SnCl_2 and SnCl_4 . For the silver salts— Ag_2O ; Ag_2Cl_2 ; Ag_2SO_4 ; $\text{Ag}_2(\text{NO}_3)_2$; Ag_2NO_3 ; &c.

Detection of Iodine in Urine in the State of Iodide of Potassium.—C. Gianetti.—This paper contains a critical review of Dr. Pellegio's published memoir "On the Best Means of Detecting Iodine in Urine."

Composition of Candle-Nuts and Kernels and Cake of Cocoa-Nuts.—Dr. G. Nallino.—The first portion of this essay treats on the chemical analysis of the so-called candle-nuts, the seed of the *Aleurites triloba*, Forst., a tree met with in some of the islands of the Pacific Ocean, as well as in the Molouques. The husks of these nuts contain, in 100 parts—Water, 3.71; organic matter, 89.90; mineral matter, 6.39. The kernels contain, in 100 parts—Water, 5.25; fatty matter (extracted by means of sulphide of carbon), 62.97; cellulose and other organic matter, 28.99; mineral matter, 2.79. The quantity

of nitrogen amounts to 3.64 per cent. The ash consists, in 100 parts, of—Lime, 18.69; magnesia, 6.01; potassa, 11.33; anhydrous phosphoric acid, 29.33. The second part of this memoir treats on the cocoa-nut cake, used as fodder for cattle after the oil has been pressed from the seed (fruit of *Cocos nucifera*, imported into Europe for extracting the oil it contains, chiefly used for soap making). 100 parts of the air-dry cake contain—Proteine substances, 21.20; fatty matter, 8.60; cellulose, 7.70; water, 9.36. The centesimal composition of the ash of this cake (carbonic acid being deducted) is—Potassa, 40.57; soda, 2.30; lime, 4.71; magnesia, 2.95; peroxide of iron, 3.54; phosphoric acid, 26.98; sulphuric acid, 3.78; silica, 3.38; chlorine, 13.42. The centesimal composition of the kernels of the cocoa-nut in natural state is—Water, 5.80; fatty matter extracted by sulphide of carbon, 67.85; cellulose and other organic matter, 24.80; ash, 1.55.

Annalen der Chemie und Pharmacie, No. 9, 1872.

This number contains the following original papers and memoirs:—

New Derivative of Styphnic Acid.—Dr. J. Schreder.—In the introduction to this paper the author refers at some length to his former researches on the subject of styphnic acid, also known as oxyphnic acid, and next treats at length on the action of cyanide of potassium upon the neutral potassa salt of the acid just mentioned. The result of this reaction (the process of preparation and purification of the crude product is described at great length) is the formation of a new body, which has been named resorcin-indophan, a substance soluble in water (the solution exhibiting a blue-violet colouration), insoluble in alcohol and ether, somewhat soluble in boiling-hot acetic acid, and readily so in concentrated sulphuric acid. The formula of this body is $\text{C}_8\text{H}_7\text{N}_3\text{O}_6$. The potassa, soda, and baryta salts of this substance are next described, and the essay winds up with a lengthy discussion on the constitutional formula of this body, this portion being elucidated by very lengthy and complex formulæ.

Some Combinations of Vinyl.—Dr. E. Baumann.—This exhaustive monograph is divided into the following sections:—Introduction, containing a condensed review of the labours of Sawitzki, Semenoff, Miasnikoff, and Dr. A. W. Hofmann on this subject; action of sodium methylate upon an excess of iodide and of bromide of vinyl at the ordinary temperature; experiments made with the view to ascertain the action of the cyanides of potassium and of silver upon bromide of vinyl; conversion of the bromide and chloride of vinyl into isomeric bodies.

Camphoric Acid.—F. Wreden.—This essay contains, in the first place, a detailed description of an improved method of preparing camphoric acid; next, a lengthy review of the results of the researches obtained by other scientific chemists who have studied camphoric acid, which is, according to the author, a bibasic acid of the formula $\text{C}_8\text{H}_8(\text{CO}_2\text{H})_2$. There exist four isomeric modifications of camphoric acid—viz., dextro- and sinistral-camphoric acids (i.e., optically active); para-camphoric acid, optically inactive; and meso-camphoric acid, discovered by the author, and obtained from the dextro-camphoric acid by the action of hydrochloric or hydriodic acids. The meso-camphoric acid is, in pure state, a solid substance in the form of needle-shaped crystals, is more soluble in water than the other camphoric acids, fuses at 113°, and readily soluble in alcohol and ether. The formula of this acid is $\text{C}_{10}\text{H}_{16}\text{O}_6$. This essay further treats on the substitution-products of camphoric acid anhydride and on amido-camphoric acid, on oxycamphoric acid anhydride (camphanic acid) and on some salts and derivatives from these bodies.

On Carbazol.—C. Graebe and C. Glaser.—Carbazol is a substance met with in crude anthracene, and has been also synthetically prepared by one of the authors by passing vapours of aniline and of diphenylamine through red-hot tubes. The preparation of carbazol from the crude material (viz., a heavy coal-tar oil) is described at very great length. In pure state, carbazol is a white-coloured, crystalline, solid substance, fusing at 238°, boiling at 357.5°, insoluble in water, but readily soluble in alcohol, ether, benzol, sulphide of carbon, glacial acetic acid, and chloroform. Carbazol is soluble, without decomposition, in concentrated sulphuric acid, yielding a somewhat yellowish brown-coloured solution, which turns to a deep green colour when the sulphuric acid contains the slightest trace of nitric acid, which strikes with carbazol a green colour. Carbazol forms sulpho- and nitro-compounds and a peculiar combination with picric acid— $\text{C}_{12}\text{H}_9\text{N}, \text{C}_6\text{H}_3(\text{NO}_2)_3\text{OH}$.

The formula of carbazol is $\text{C}_{12}\text{H}_9\text{N}$; considered as imido-diphenyl the formula is—

Ethyl-carbazol, $\text{C}_{14}\text{H}_{13}(\text{C}_2\text{H}_5\text{O})\text{N}$, and carbazoline, $\text{C}_{13}\text{H}_{11}\text{N}$ (the product of the reaction ensuing when carbazol is heated along with phosphorus and hydriodic acid), are described at length, as is also hydrocarbazol, $\text{C}_{15}\text{H}_{13}\text{N}$.

Vapour Densities of Some Aromatic Compounds of High Boiling-Point.—C. Graebe.—This essay possesses high scientific merits, and it is elucidated by several tables exhibiting results of experiments. Its contents are not, however, suited for useful abstraction.

Les Mondes, August 1, 1872.

This number contains no original matter relating to chemistry or collateral subjects.

Polytechnisches Journal von Dr. E. M. Dingler, first number for July, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

New Form of Noë's Thermo-Electric Element.—A. von Waltenhofen.—The detailed description, illustrated by an engraving, of an improved thermo-electric element suited for therapeutic and other induction apparatus.

Contribution to the Technology of Glass.—E. Siegwart.—This exhaustive essay treats on the history of the discovery of glass, its modes of manufacture, and the present condition of the industry.

Preparation of Thallium on the Large Scale.—M. Schaffner.

Sulpho-Acids of Aniline Blue.—E. Bulk.—This essay treats on—Triphenyl-rosanilin-monosulpho acid (the soda-salt of which is known as Nicholson's blue, or alkali blue; the acid is monobasic); triphenyl-rosanilin-disulpho acid (the soda-salt of this acid is known in practice as soluble blue); triphenyl-rosanilin-trisulpho acid; triphenyl-rosanilin-tetrasulpho acid (the highest sulpho-compound obtainable from aniline blue by the action of sulphuric acid; it is soluble in water, with a blue colour; its alkaline and other salts are readily soluble in water, but insoluble in alcohol). Aniline violet also yields sulpho-acids, but not so readily as aniline blue.

Manufacture of Chili Saltpetre (Nitrate of Soda) and of Iodine at Tarapaca, Peru.—Dr. R. Wagner.—This essay contains statistical figures of the quantities of nitrate of soda obtained daily in eleven of the larger works, the production of which varies from 200 to 1200 cwt. The quantity of iodine met with in 1 litre of the mother-liquors of the works alluded to was found to vary from 2.30 to 4.80 grms.

Embalming Composition.—Dr. Bufaline.—For the purpose especially of preserving cadavers for anatomical use, the author recommends the following mixture:—Camphor and pure carbolic acid, each, 70 grms.; paraffin oil, 200 grms. This fluid is either applied by injection into the blood vessels, or the parts of the cadaver to be kept are soaked in it.

The American Journal of Science and Arts, July, 1872.

With the exception of two papers which we reserve for full reproduction, this number contains no original papers relating to chemistry.

Bulletin de l'Académie Impériale des Sciences de St. Petersburg, Vol. xvii., No. 4.

New Variety of Hexylen.—N. Tschakowsky.—After briefly referring to the hexylenes discovered and described by Drs. Erlenmeyer, Buff, and Wanklyn, the author states that, starting from methyl-diethyl-carbinol (obtained by causing chloride of acetyl to act upon zinc ethyl), he has converted that alcohol, first into its corresponding iodide, by means of gaseous iodic acid, and next this compound has been treated in a sealed tube at 200° with alcoholic caustic potassa solution. Hereby a liquid colourless hydrocarbon was obtained boiling at from 68° to 72°. The vapour density of this body, referred to air, is 2.908; referred to hydrogen, 44.900. The simplest formula is C_6H_{12} ; but the constitutional formula, which, when combined with hydriodic acid, forms the tertiary iodide of methyl-diethyl-carbinol, are—

The first of these formulæ is considered by the author as the most correct; but further research, and the behaviour of this new hexylen with hypochlorous acid will settle this point.

La Revue Scientifique de la France et de l'Etranger, July 20, 1872.

The Chemical Manures Judged by Tradition.—Dr. G. Ville.—The opening discourse of the experimental lectures on practical agriculture at Vincennes.

July 27, 1872.

This number contains no original papers relating to chemistry, but we call attention to the following physiological essay:—

Chemical Modifications which the Secretions Undergo under the Influence of Substances which Modify the Blood Globules.—Dr. Ritter.

Preis Conrants der Fabrik für Alkohol-Präparate, von C. A. F. Kahlbaum, Berlin.

This catalogue of chemical preparations shows rapid advances of manufacturing chemistry in Germany, many rare and complex substances being quoted as regularly prepared. Under the section Methyl-Alcohol, for instance, we meet with methyl-cyanide, trimethylamine, methylen-iodide, and tetrachloride of carbon.

NOTES AND QUERIES.

Glacial Sulphuric Acid.—(Reply to S. R. P.)—This acid may be obtained from Dr. L. O. Marquart, Bonn, at 8 shalers per kilogramme net.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND CO., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

North London School of Chemistry, Pharmacy, &c.

For instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has had laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871—1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied by a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—34, KENTISH TOWN ROAD, N.W.

THE CHEMICAL NEWS.

VOL. XXVI. No. 664.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

BRIGHTON MEETING, AUGUST 14, 1872.

INAUGURAL ADDRESS OF THE PRESIDENT,

WILLIAM B. CARPENTER, M.D., LL.D., F.R.S.,

Registrar of the University of London.

MY LORDS, LADIES, AND GENTLEMEN,—

THIRTY-SIX years have now elapsed since at the first and (I regret to say) the only meeting of this Association held in Bristol,—which ancient city followed immediately upon our national universities in giving it a welcome,—I enjoyed the privilege which I hold it one of the most valuable functions of these annual assemblages to bestow; that of coming into personal relation with those distinguished men whose names are to every cultivator of science as “household words,” and the light of whose brilliant example, and the warmth of whose cordial encouragement are the most precious influences by which his own aspirations can be fostered and directed. Under the Presidency of the Marquis of Lansdowne, with Conybeare and Prichard as Vice-Presidents, with Vernon Harcourt as General Secretary, and John Phillips as Assistant Secretary, were gathered together Whewell and Peacock, James Forbes and Sir W. Rowan Hamilton, Murchison and Sedgwick, Buckland and De la Beche, Henslow and Daubeny, Roget, Richardson, and Edward Forbes, with many others, perhaps not less distinguished, of whom my own recollection is less vivid.

In his honoured old age, Sedgwick still retains, in the academic home of his life, all his pristine interest in whatever bears on the advance of the science he has adorned as well as enriched; and Phillips still cultivates with all his old enthusiasm the congenial soil to which he has been transplanted. But the rest,—our fathers and elder brothers—“Where are they?” It is for us of the present generation to show that they live in our lives; to carry forward the work which they commenced; and to transmit the influence of their example to our own successors.

There is one of these great men, whose departure from among us since last we met claims a special notice, and whose life—full as it was of years and honours—we should have all desired to see prolonged for a few months, could its feebleness have been unattended with suffering. For we should all then have sympathised with Murchison, in the delight with which he would have received the intelligence of the safety of the friend in whose scientific labours and personal welfare he felt to the last the keenest interest. That this intelligence, which our own expedition for the relief of Livingstone would have obtained (we will hope) a few months later, should have been brought to us through the generosity of one, and the enterprising ability—may I not use our peculiarly English word, the “pluck”—of another of our American brethren, cannot but be a matter of national regret to us. But let us bury that regret in the common joy which both nations feel in the result; and while we give a cordial welcome to Mr. Stanley, let us glory in the prospect now opening, that England and America will co-operate in that noble object which—far more than the discovery of the sources of the Nile—our

great traveller has set before himself as his true mission, the extinction of the slave trade.

At the last meeting of this Association, I had the pleasure of being able to announce that I had received from the First Lord of the Admiralty a favourable reply to a representation I had ventured to make to him as to the importance of prosecuting on a more extended scale the course of inquiry into the physical and biological conditions of the deep sea, on which, with my colleagues, Professor Wyville Thomson and Mr. J. Gwyn Jeffries, I had been engaged for the three preceding years. That for which I had asked was a circumnavigating Expedition of at least three years' duration, provided with an adequate scientific staff, and with the most complete equipment that our experience could devise. The Council of the Royal Society having been led by the encouraging tenor of the answer I had received, to make a formal application to this effect, the liberal arrangements of the Government have been carried out under the advice of a scientific committee which included representatives of this Association. H.M.S. *Challenger*, a vessel in every way suitable for the purpose, is now being fitted out at Sheerness; the command of the Expedition is entrusted to Captain Nares, an officer of whose high qualifications I have myself the fullest assurance; while the scientific charge of it will be taken by my excellent friend Professor Wyville Thomson. At whose suggestion it was that these investigations were originally commenced, and whose zeal for the efficient prosecution of them is shown by his relinquishment for a time of the important academic position he at present fills. It is anticipated that the Expedition will sail in November next; and I feel sure that the good wishes of all of you will go along with it.

The confident anticipation expressed by my predecessor that, for the utilisation of the total eclipse of the sun then impending, our Government would “exercise the same wise liberality as heretofore in the interests of science,” has been amply fulfilled. An Eclipse Expedition to India was organised at the charge of the Home Government, and placed under the direction of Mr. Lockyer; the Indian Government contributed its quota to the work; and a most valuable body of results was obtained, of which, with those of the previous year, a report is now being prepared under the direction of the Council of the Astronomical Society.

It has been customary with successive occupants of this chair, distinguished as leaders in their several divisions of the noble army of science, to open the proceedings of the meetings over which they respectively presided with a discourse on some aspect of Nature in her relation to man. But I am not aware that any one of them has taken up the other side of the enquiry,—that which concerns man as the “interpreter of Nature;” and I have therefore thought it not inappropriate to lead you to the consideration of the mental processes by which are formed those fundamental conceptions of matter and force, of cause and effect, of law and order, which furnish the basis of all scientific reasoning, and constitute the *philosophia prima* of Bacon. There is a great deal of what I cannot but regard as fallacious and misleading philosophy—“oppositions of science falsely so-called”—abroad in the world at the present time. And I hope to satisfy you that those who set up *their own conceptions* of the orderly sequence which they discern in the phenomena of nature as fixed and determinate *laws*, by which those phenomena not only *are* within all human experience, but *always have been*, and *always must be*, invariably governed, are really guilty of the intellectual arrogance they condemn in the systems of the ancients, and place themselves in diametrical antagonism to those real philosophers, by whose comprehensive grasp and penetrating insight that order has been so far disclosed. For what love of the truth as it is in nature was ever more conspicuous than that which Kepler displayed, in his abandonment of each of the ingenious conceptions of the planetary system which his

fertile imagination had successively devised, so soon as it proved to be inconsistent with the facts disclosed by observation? In that almost admiring description of the way in which his enemy Mars, "whom he had left at home a despised captive," had "burst all the chains of the equations, and broke forth from the prisons of the tables," who does not recognise the justice of Schiller's definition of the real philosopher as one who always loves truth better than his system? And when at last he had gained the full assurance of a success so complete that (as he says) he thought he must be dreaming, or that he had been reasoning in a circle, who does not feel the almost sublimity of the self-abnegation with which, after attaining what was in his own estimation such a glorious reward of his life of toil, disappointment, and self-sacrifice, he abstains from claiming the applause of his contemporaries, but leaves his fame to after ages in these noble words: "The book is written; to be read either now or by posterity, I care not which. It may well wait a century for a reader, as God has waited six thousand years for an observer."

And when a yet greater than Kepler was bringing to its final issue that grandest of all scientific conceptions, long pondered over by his almost superhuman intellect,—which linked together the heavens and the earth, the planets and the sun, the primaries and their satellites, and included even the vagrant comets, in the *nexus* of a universal attraction—establishing for all time the truth for whose utterance Galileo had been condemned, and giving to Kepler's laws a significance of which their author had never dreamed,—what was the meaning of that agitation which prevented the philosopher from completing his computation, and compelled him to hand it over to his friend? That it was not the thought of his own greatness, but the glimpse of the grand universal order thus revealed to his mental vision, which shook the serene and massive soul of Newton to its foundations, we have the proof in that beautiful comparison in which he likened himself to a child picking up shells on the shore of the vast ocean of truth—a comparison which will be evidence to all time at once of his true philosophy and his profound humility.

Though it is with the intellectual representation of nature which we call *Science*, that we are primarily concerned, it will not be without its use to cast a glance in the first instance at the other two principal characters under which man acts as her interpreter,—those, namely, of the artist and of the poet.

The artist serves as the interpreter of Nature, not when he works as the mere copyist, delineating that which he sees with his bodily eyes, and which we could see as well for ourselves; but when he endeavours to awaken within us the perception of those beauties and harmonies which his own trained sense has recognised, and thus impart to us the pleasure he has himself derived from their contemplation. As no two artists agree in the original constitution and acquired habits of their minds, all look at Nature with different (mental) eyes; so that to each, *Nature is what he individually sees in her*.

The poet, again, serves as the interpreter of Nature, not so much when by skilful word-painting (whether in prose or verse) he calls up before our mental vision the picture of some actual or ideal scene, however beautiful; as when, by rendering into appropriate forms those deeper impressions made by the nature around him on the moral and emotional part of his own nature, he transfers these impressions to the corresponding part of ours. For it is the attribute of the true poet to penetrate the secret of those mysterious influences which we all unknowingly experience; and having discovered this to himself, to bring others, by the power he thus wields, into the like sympathetic relation with Nature,—evoking with skilful touch the varied response of the soul's finest chords, heightening its joys, assuaging its griefs, and elevating its aspirations. Whilst, then, the artist aims to picture what he *sees* in Nature, it is the object of the poet

to represent what he *feels* in Nature; and to each true poet, *Nature is what he individually finds in her*.

The philosopher's interpretation of Nature seems less individual than that of the artist or the poet, because it is based on facts which anyone may verify, and is elaborated by reasoning processes of which all admit the validity. He looks at the Universe as a vast book lying open before him, of which he has in the first place to learn the characters, then to master the language, and finally to apprehend the ideas which that language conveys. In that book there are many chapters, treating of different subjects; and as life is too short for any one man to grasp the whole, the scientific interpretation of this book comes to be the work of many intellects, differing not merely in the range but also in the character of their powers. But whilst there are "diversities of gifts," there is "the same spirit." While each takes his special direction, the general method of study is the same for all. And it is a testimony alike to the truth of that method and to the unity of Nature, that there is an ever-increasing tendency towards agreement among those who use it aright;—temporary differences of interpretation being removed, sometimes by a more complete mastery of her language, sometimes by a better apprehension of her ideas;—and lines of pursuit which had seemed entirely distinct, or even widely divergent, being found to lead at last to one common goal. And it is this agreement which gives rise to the general belief—in many, to the confident assurance—that the scientific interpretation of Nature represents her not merely as she *seems*, but as she *really is*.

When, however, we carefully examine the foundation of that assurance, we find reason to distrust its security; for it can be shown to be no less true of the scientific conception of nature, than it is of the artistic or the poetic, that it is a *representation framed by the mind itself* out of the materials supplied by the impressions which external objects make upon the senses; so that to each man of science, *nature is what he individually believes her to be*. And that belief will rest on very different bases, and will have very unequal values, in different departments of science. Thus in what are commonly known as the "exact" sciences, of which astronomy may be taken as the type, the data afforded by precise methods of observation can be made the basis of reasoning, in every step of which the mathematician feels the fullest assurance of certainty; and the final deduction is justified either by its conformity to known or ascertainable facts,—as when Kepler determined the elliptic orbit of Mars; or by the fulfilment of the predictions it has sanctioned,—as in the occurrence of an eclipse or an occultation at the precise moment specified many years previously; or, still more emphatically, by the actual discovery of the phenomena till then unrecognised,—as when the perturbations of the planets, shown by Newton to be the necessary results of their mutual attraction, were proved by observation to have a real existence; or as when then the unknown disturber of Uranus was found in the place assigned to him by the computations of Adams and Le Verrier.

We are accustomed, and I think most rightly, to speak of these achievements as triumphs of the human intellect. But the very phrase implies that the work is done by mental agency; and the coincidence of its results with the facts of observation is far from proving the intellectual process to have been correct. For we learn from the honest confessions of Kepler, that he was led to the discovery of the elliptic orbit of Mars by a series of happy accidents, which turned his erroneous guesses into the right direction; and to that of the passage of the Radius Vector over equal areas in equal times, by the notion of a whirling force emanating from the sun, which we now regard as an entirely wrong conception of the cause of orbital revolution.* It should always be remembered, moreover, that the Ptolemaic system of astronomy, with all its cumbrous ideal mechanism of "Centric and Excentric, Cycle and

* See Drinkwater's "Life of Kepler," in the Library of Useful Knowledge, pp. 26 to 35.

Epicyle, Orb in Orb," did intellectually represent all that the astronomer, prior to the invention of the telescope, could see from his actual standpoint, the earth, with an accuracy which was proved by the fulfilment of his anticipations. And in that last and most memorable prediction which has given an imperishable fame to our two illustrious contemporaries, the inadequacy of the basis afforded by actual observation of the perturbations of Uranus, required that it should be supplemented by an assumption of the probable distance of the disturbing planet beyond, which has been shown by subsequent observation to have been only an approximation to the truth.

Even in this most exact of sciences, therefore, we cannot proceed a step, without translating the actual phenomena of nature into intellectual representations of those phenomena; and it is because the Newtonian conception is not only the most simple, but is also, up to the extent of our present knowledge, *universal* in its conformity to the facts of observation, that we accept it as the only scheme of the universe yet promulgated which satisfies our intellectual requirements.

When, under the reign of the Ptolemaic System, any new inequality was discovered in the motion of a planet, a new wheel had to be added to the ideal mechanism,—as Ptolemy said, "to save appearances." If it should prove, a century hence, that the motion of Neptune himself is disturbed by some other attraction than that exerted by the interior planets, we should confidently expect that not an *ideal* but a *real* cause for that disturbance will be found in the existence of another planet beyond. But I trust that I have now made it evident to you, that this confident expectation is not justified by any absolute necessity of Nature, but arises entirely out of *our belief* in her uniformity; and into the grounds of this and other primary beliefs, which serve as the foundation of all scientific reasoning, we shall presently inquire.

There is another class of cases, in which an equal certainty is generally claimed for conclusions that seem to flow immediately from observed facts, though really evolved by intellectual processes; the apparent simplicity and directness of those processes either causing them to be entirely overlooked or veiling the assumptions on which they are based. Thus Mr. Lockyer speaks as confidently of the sun's chromosphere of incandescent hydrogen, and of the local outbursts which cause it to send forth projections tens of thousands of miles high, as if he had been able to capture a flask of this gas, and had generated water by causing it to unite with oxygen. Yet this confidence is entirely based on the assumption, that a certain line which is seen in the spectrum of a hydrogen flame, *means* hydrogen also when seen in the spectrum of the sun's chromosphere; and high as is the probability of that assumption, it cannot be regarded as a demonstrated certainty, since it is by no means inconceivable that the same line *might* be produced by *some other* substance at present unknown. And so when Dr. Huggins deduces from the different relative positions of certain lines in the spectra of different stars that these stars are moving from or towards us in space, his admirable train of reasoning is based on the assumption that these lines have *the same meaning*—that is, that they *represent the same elements*—in every luminary. That assumption, like the preceding, may be regarded as possessing a sufficiently high probability to justify the reasoning based upon it; more especially since, by the other researches of that excellent observer, the same chemical elements have been detected as vapours in those filmy cloudlets which seem to be stars in an early stage of consolidation. But when Frankland and Lockyer, seeing in the spectrum of the yellow solar prominences a certain bright line not identifiable with that of any known terrestrial flame, attribute this to a hypothetical new substance which they propose to call Helium, it is obvious that their assumption rests on a far less secure foundation; until it shall have received that verification, which, in the case of Mr. Crookes's researches on Thallium, was afforded by the actual discovery of the

new metal, whose presence had been indicated to him by a line in the spectrum not attributable to any substance then known.

In a large number of other cases, moreover, our scientific interpretations are clearly matters of *judgment*; and this is eminently a *personal act*, the value of its results depending in each case upon the qualifications of the *individual* for arriving at a correct decision. The surest of such judgments are those dictated by what we term "common sense," as to matters on which there seems no room for difference of opinion, because every sane person comes to the same conclusion, although he may be able to give no other reason for it than that it appears to him "self-evident." Thus while philosophers have raised a thick cloud of dust in the discussion of the basis of our belief in the existence of a world external to ourselves,—of the Non Ego, as distinct from the Ego,—and while every logician claims to have found some flaw in the proof advanced by every other,—the common sense of mankind has arrived at a decision that is practically worth all the arguments of all the philosophers who have fought again and again over this battle-ground. And I think it can be shown that the trustworthiness of this common sense decision arises from its dependence, not on any one set of experiences, but upon our *unconscious co-ordination of the whole aggregate of our experiences*,—not on the conclusiveness of any one train of reasoning, but on the *convergence of all our lines of thought towards this one centre*.

Now this "common sense," disciplined and enlarged by appropriate culture, becomes one of our most valuable instruments of scientific inquiry; affording in many instances the best, and sometimes the only, basis for a rational conclusion. Let us take as a typical case, in which no special knowledge is required, what we are accustomed to call the "flint implements" of the Abbeville and Amiens gravel-beds. No logical proof can be adduced that the peculiar shapes of these flints were given to them by human hands; but does any unprejudiced person now doubt it? The evidence of *design*, to which, after an examination of one or two such specimens, we should only be justified in attaching a probable value, derives an irresistible cogency from accumulation. On the other hand, the *improbability* that these flints acquired their peculiar shape by *accident*, becomes to our minds greater and greater as more and more such specimens are found; until at last this hypothesis, although it cannot be directly disproved, is felt to be almost inconceivable, except by minds previously "possessed" by the "dominant idea" of the modern origin of man. And thus what was in the first instance a matter of discussion, has now become one of those "self-evident" propositions, which claim the unhesitating assent of all whose opinion on the subject is entitled to the least weight.

We proceed upwards, however, from such questions as the common sense of mankind generally is competent to decide, to those in which special knowledge is required to give value to the judgment; and thus the interpretation of Nature by the use of that faculty comes to be more and more *individual*; things being perfectly "self-evident" to men of special culture which ordinary men, or men whose training has lain in a different direction, do not apprehend as such. Of all departments of science, geology seems to me to be the one that most depends on this specially-trained "common sense;" which brings as it were into one focus the light afforded by a great variety of studies,—Physical and Chemical, Geographical and Biological; and throws it on the pages of that Great Stone Book, on which the past history of our globe is recorded. And whilst astronomy is of all sciences that which may be considered as most nearly representing Nature as she really is, geology is that which most completely represents her as seen through the medium of the interpreting mind; the meaning of the phenomena that constitute its data being in almost every instance open to question, and the judgments passed upon the

strictly chemical; the electrolytic cell does our work; and indeed we claim half the electric telegraph, for while the needle may oscillate in Section A, the battery belongs to B.

Last in Section A comes meteorology; and there are chemical questions concerning the constitution of the atmosphere, its changes, and the effect of its occasional constituents upon vegetable and animal life, which merit the deepest attention of the physiologist, philanthropist, and statesman.

If we turn to Section C, there is an outlying province belonging to us, namely, mineralogy, which lies on the frontiers of geology. A vast and very promising region is the origin and mode of formation of different minerals: this has attracted some explorers during the past year; but in order to investigate it properly the geologist and the chemist must travel hand in hand. Geology, in demanding of us the analysis of earths and ores, rocks and precious stones, repays us by bringing to our knowledge many a rare element and strange combination.

When we pass from C to D, that is from the crust of the globe to the organised beings that inhabit and adorn it, we are introduced into new regions of research. When organic chemistry was young, Cuvier said of it, "*Dans cette nouvelle magie, le chimiste n'a presque qu'à vouloir: tout peut se changer en tout; tout peut l'extraire de tout;*" and though we have now learnt much of the laws by which these magical transformations proceed, they far transcend the dreams of the French philosopher; there is yet no visible limit to the multitude of products to be derived from the vegetable and animal world, and their changes seem to afford boundless scope for chemical ingenuity. The benefit here also is reciprocal; for the physiologist enters by our aid into the wonderful laboratory of the living plant or animal, and learns to estimate the mode of action of different foods and medicines. There have lately been some good researches of this character; the difficulties are great, but the results to be achieved are worthy of any effort.

There may be little intercourse between us and the geographers in E, but we stand in no distant relationship with many of the subjects discussed in F. Economic science embraces the chemical arts from cookery upwards; such imperial questions as that of the national standards, or the patent laws, interest us greatly; the yield of our corn-fields is increased through our knowledge of the constituents of soils and manures, and upon many of the chemical manufactures depend in no small degree the commerce and the wealth of Britain.

In this most important branch of technical chemistry we need the skill of the mechanician; and this introduces us to Section G. One of the questions of the day will illustrate the connexion between these varied departments of study. Statistics prove that the consumption of coal is now advancing, not at the gradual pace which recent calculations allowed, but at a rapidly accelerating speed, and they make the householder anxious about rising prices, and the political economist about the duration of our coal-fields. It is well known that there is a great waste of fuel throughout the country, as the maximum of heat produced by the combustion is very far from being ever utilised; and it will be for the combined wisdom of the chemist, physicist, and mechanician to devise means for reducing this lavish expenditure, or to indicate other available sources of power.

While this correlation of the natural sciences renders it desirable that the votary of one should have some general acquaintance with the rest, the correlation of all knowledge shows that no education can be complete which ignores the study of nature. A mind fed only on one particular kind of lore, however excellent that kind may be, must fail of proper nourishment. I am not going to say a word against philological studies: I am too fond of them myself for that; and I could wish that the

modern languages were taught more, and the classic languages were taught better than they are at present. What I do contend for is, that chemistry (or some cognate branch of science) should have an honoured place in the education of every English lady and gentleman. I say purposely "an honoured place;" for at present where chemistry is introduced we too often find the idea latent which was expressed by one principal of a lady's college, who told a friend of mine that he was to give the girls a course of pretty experiments, but that she did not expect him to teach them anything; and we know that when boys repeat chemical experiments at home it is looked upon as an amusement, a philosophical one no doubt, but rather objectionable, inasmuch as they spoil their mother's towels, and singe their own eyebrows.

Of course some knowledge of chemistry is indispensable for a large number of our manufacturers, and for the medical profession, while it is extremely valuable to the farmer, the miner, and the engineer. It will also be readily granted that information about the air we breathe, the water we drink, the food we live upon, the fuel we burn, and the various common objects we handle, must be of service to every man. But we are met by the advocates of the old system of education with the remark that the value of school-teaching does not depend so much upon the information given as upon the mental training. This I admit: though it seems to me that if the same training can be secured by two studies, the one of which (like the making of Latin verses) gives no information at all, and the other (like chemical analysis) imparts some useful knowledge, we should prefer the latter. But I hold that as a means of educating the mental faculties, chemistry, faithfully taught, has in many respects the advantage over literary studies. There is superabundant scope for the exercise of the memory; the powers of observation are developed by it to a wonderful degree; the reasoning powers may be well disciplined on the philosophy of chemical change, or the application of the laws of Dalton, Mitscherlich, and Avogadro; while the imagination may be cultivated by the attempt to form a conception of the ultimate particles of matter, with their affinities and atomicities, as they act and react upon one another under the control of the physical forces. And I might speak of higher considerations than mere intellectual culture; for surely the works of the Allwise and Bountiful Creator are a more truthful and a purer subject of contemplation for the opening minds of youth, and more in accordance with Christian ideas, than are the crude notions of a past stage of civilisation, and the ignorant and gross fancies of a defunct paganism.

There is another requirement in education—the training of the mind to the discovery and recognition of truth. For this purpose philological studies have no fitness; mathematical studies, though peculiarly adapted for it, apply only to cases where demonstrative proof is possible; but the study of physical science is remarkably well fitted for teaching the proper methods of inquiry, and the strict relations between theory and fact. Now the historian, the politician, the mental philosopher, the theologian, or any one else who desires to influence the thoughts of his fellow men, should be in a position to distinguish between truth and error in his own department; and his mind may be well disciplined for this by a study which is less liable to be disturbed by human passions, predilections, or wishes, and where the conclusions are more readily brought to the test of observation or experiment.

Our Government insists on a certain standard of education for all who are allowed to teach in our elementary schools. In those schools which receive no state aid it is only public opinion which can insist that the teacher shall be duly qualified himself. Such bodies as the British Association form this public opinion, and will deserve well of their country if they demand that these masters and mistresses shall know something of the material universe in which they move, and be able to

impart to every child such scientific knowledge as shall afford him an interesting subject for thought, give him useful information, and discipline his mental powers.

Among the many services rendered by the monthly reports of the progress of chemistry which the Chemical Society publishes, and the British Association helps to pay for, there is one which is rather salutary than pleasant. They bring prominently before our notice the fact that in the race of original research we are being distanced by foreign chemists. I refer, not to the quality of our work, about which opinions will probably differ, but to the quantity, which can be determined by very simple arithmetic. This is a matter of no small importance, not only for the honour of England, but still more for the advancement of science and the welfare of man. From the Physical Chair of this Association last year, a note of warning was uttered in the following words, after a reference to the sad fate of Newton's successors who allowed mathematical science almost to die out of the country:—"If the successors of Davy and Faraday pause to ponder even on their achievements, we shall soon be again in the same state of ignominious inferiority." The President of the Chemical Society also, in the last Anniversary Address, drew attention to the diminished activity of chemical discovery, and to the lamentable fewness of original papers communicated. He traces this chiefly to "the non-recognition of experimental research by our universities," and suggests that in granting of science-degrees every candidate should be required, as in Germany, to prove his ability for original investigation.

Concurring in this, I would remark that other causes have also been assigned, and other suggestions have been made. There is the small recognition of original research even by our learned societies—at least such recognition as will come home to the understanding of the general public. It is true the fellowship of the Royal Society is awarded mainly for original discoveries, and there are two or three medals to be disposed of annually; but these distinctions fall to the lot of the seniors in science, often men who are beyond the need of encouragement; and though they doubtless are serviceable as incentives, there is many a beginner in the honourable contest of discovery who is too modest even to hope for the blue ribbon of science. While the Victoria Cross is awarded to few, every soldier who has borne part in a victory expects his clasp; and so might every man who has won victories over the secrets of nature fairly look for some public recognition. It has been suggested, for instance, that the Royal Society, in addition to the F.R.S., might institute an Associateship, with the letters A.R.S., designed exclusively for those younger men who have shown zeal and ability in original research, but whose discoveries have not been sufficient to entitle them already to the Fellowship. It is suggested, too, that the Chemical Society might give some medal, or diploma, or some similar distinction, to those who contribute papers of sufficient merit.

But beyond this is the non-recognition of scientific research by society in general. We can scarcely expect the average enlightened Englishman to be anything but scared by a graphic formula, or a doubly sesquipedalian word containing two or three compound radicals; but he need not continue to talk of the four elements, or of acids being neutralised by sugar. But, indeed, the so-called educated classes in England are not only supremely ignorant of science, they have scarcely yet arrived at the first stage of improvement—the knowledge of their own ignorance. Then, again, there is the excessive preference of practical inventions over theoretical discoveries; or rather, perhaps, the inability to appreciate anything but tangible results. Thus a new aniline compound is nothing unless it will dye a pretty colour; if we speak of the discovery of a new metal by the spectroscope, they simply

ask—What is it useful for? and the rigorous determination of an atomic weight has for them no meaning nor interest nor beauty. The general appreciation of science must be of gradual growth; yet there are wealthy men who know its value, and who might well become the endowers of research. There are, indeed, at present funds available for the purpose—such as the Government Grant, and the surplus funds of this Association; but the money is given simply to cover actual outlay, and this, though very useful, scarcely meets the case of those young philosophers who have no balance at their bankers, and yet must live. Will not some of these wealthy men endow experimental scholarships, or professorships, in connection with our colleges, institutions, or learned societies? As an instance of the good that may be effected in this way, may be cited the Fullerian professorships; and as a very recent example, worthy of all honour, may be mentioned the purpose of Mr. J. B. Lawes, not only to continue his elaborate experiments at Rothamsted throughout his lifetime, but to place his laboratory and experimental fields in trust, together with £100,000, so that investigations may be continued in the wider and more scientific questions which the progress of agriculture may suggest.

The Government of our country, through the Science and Art Department, renders good assistance to the teaching of science, and if the recommendations of the Royal Commission on Scientific Instruction and the Advancement of Science be adopted, the introduction of practical examinations for the obtaining of certificates for a superior grade of science-master will certainly foster a spirit of research. It has been generally held that the promotion of research is within the legitimate scope of Government; and where, as in the case of Aristotle and Alexander, genius and industry have been sustained by princely munificence, the happiest results have ensued. Yet this question of Government aid is a delicate one: for genius, when put into swaddling clothes, is apt to be stifled by them; and were science to depend on political favour or imperial support, it would be a fatal calamity. Still I think it will be everywhere admitted that science might with propriety be subsidised from the public funds in cases where the results may be expected to confer a direct benefit upon the community, and where the inquiry, either from its expense, its tediousness, its uninteresting character, or the amount of co-operation required, is not likely to be carried out by voluntary effort. The astronomical work which is paid for by Government bears upon navigation, and answers both these requirements; and it is easy to conceive of inquiries in our own science that might equally deserve the assistance of the State. Some of these might also more than repay the outlay, though perhaps the profit would not fall into next year's budget.

I believe that this diminution of original research, which we deplore, is partly due to a cause in which we rejoice—the recent extension of science-teaching. The professorships of chemistry are scarcely more numerous now than they were twenty years ago, while the calls upon the professor's time in conducting classes, or looking over examination papers, have greatly augmented. Thus some of the most capable men have been drawn away from the investigation of nature; and in order to afford them sufficient leisure for the purpose, means must be found to multiply the number of the professorships in our various colleges.

While the rudiments of science are being infused into our primary education, now happily becoming national, while physical science is gradually gaining a footing in our secondary and our large public schools, and while it is winning for itself an honourable place at our universities, it is to be hoped that many new investigations will arise, and that British chemists will not fall behind in the upward march of discovery, but will continue hand in hand with their continental brethren thus to serve their own and future generations.

THE ANALYSIS OF WATERS IN INDIA.*

By EDWARD NICHOLSON, F.C.S.,
Assistant Surgeon R.A., Analyst of Waters, Mysore, Northern and
Ceded Districts.

(Concluded from p. 65).

PASSING now to the more important quantitative analysis we find the processes indicated hardly more trustworthy than those already noticed. The first determination does not look promising:—

"Total solids.—Evaporate to dryness half a litre of the water (or a litre or more) The evaporation is preferably carried on from first to last in a platinum capsule, but the evaporation may be carried to a small bulk in a porcelain capsule, and the residue transferred by the aid of a wash bottle and a very flexible steel spatula, to the weighed platinum capsule in which the operation is to be completed."

I need hardly say that however flexible be the spatula, the operation thus sanctioned would be fatal to any pretensions of accuracy, and it seems rather superfluous to add, "Whichever plan is adopted, the capsule should be protected during the operation with a piece of filtering paper to keep out dust."

The next process is scarcely more commendable:—

"Silica.—Treat the ignited residue with dilute hydrochloric acid, taking care to avoid loss by effervescence, dilute with water, and if the silica is in any quantity, or if an exact analysis is required, collect it in a filter, wash, dry, ignite, and weigh."

In these directions the necessary ignition of the liberated and soluble silicic acid is omitted, so that whether the analyst collects such silicic acid as may perchance be visible, or whether he avails himself of the permission to neglect it, the chances of accuracy are not much affected. It will be remarked that the show of accuracy in the caution against loss by effervescence, or gain by fortuitous dust, is accompanied by neglect to mention the most necessary precautions, and by permission to pass over a substance like silicic acid, often amounting to a fourth or a third of the whole solid constituents of a water.†

These are, however, trifling sins compared to the following gross inaccuracy in the process given for the determination of alkaline chlorides:—

"Add some chloride of ammonium (to convert sulphate of sodium or potassium into the chloride), evaporate, ignite, and weigh the residual chloride of sodium and potassium. If the water contain only a small proportion of sulphuric acid, the addition of the chloride of ammonium will suffice for the conversion of the sulphates into chlorides; but if the proportion of sulphuric acid is large, it is necessary to add at once before the addition of the milk of lime a quantity of chloride of barium equivalent to the known amount of the sulphuric acid."

The author of the scheme here distinctly commits himself to the statement that ignition of sodium sulphate with ammonium chloride changes the former into sodium chloride. Little or much sulphuric acid can make no difference in the reaction. *This statement is without the slightest foundation in fact.* Sodium sulphate ignited even with a considerable excess of ammonium chloride shows no signs of change, the weight remains unaltered, and the solution of the residue gives no indication of chloride being present. The experiment is easy to perform, so that anyone can test for himself the accuracy of the statement I here challenge. The reactions of ammonium salts (sulphate, chloride, carbonate) on the mineral constituents of water are cardinal points in water analysis, and I have no hesitation in expressing my opinion that the above statement is in itself sufficient for the rejection of the scheme compiled by the Chemical Examiner to the Government of India.

* Communicated by the Author.

† An Indian water containing 30 to 40 c.grms. per litre of solids will often contain 10 to 12 c.grms. of silica.

In conclusion I beg to disclaim any cavillous spirit in thus drawing attention to the fallacies of the three schemes of water analysis which have succeeded one another during the last two years. Had I remained silent I should have failed in the duty I owe to my profession as a chemist. I have endeavoured, in as moderate a manner as possible, to expose errors which are unfortunately too often overlooked in the desire of the medical profession for a royal road to a science which nothing but long practical experience can teach. In the course of these papers I have fixed as much as possible on certain points where any objector could join issue with me, but I have met with no reply, save in a single instance—that of my experience with the albumenoid ammonia process for the estimation of organic matter.*

With this exception my criticisms of the authorised methods of analysis have met with no defence, and I think that it is now time for action to be taken on this question.

The necessity of a sound system for the chemical examination of waters is obvious; as long as the results obtained are erroneous,—as long as not only the quantity but the very presence of the substances found is uncertain in the highest degree—so long will sanitary science endeavour in vain to formulate the qualities distinctive of good and bad water. The laws by which the Bengal Chemical Examiner judges waters are given in the Sixth Report on the Analysis of Waters, they are entirely compiled from English theories, and would have condemned every water in Bengal, had not the wretched mode of examination prescribed defeated their rigorous provisions. They may be thus summarised.

(There are nine or ten defects possible in a water, anyone of which is strong evidence of sewage contamination, but the absence of any or all of them is no proof that the water has not at some previous time been polluted.)

When we find that these lynch laws and these peculiar rules of evidence are joined to a system of examination so defective that waters are condemned as foul for the most doubtful reasons, while it totally fails to elicit the facts on which judgment should be based, it is evidently high time for reform in that department of science which has so long passed for chemistry in India.

A few examples of the chemical evidence current in Bengal may here be quoted. The waters of the station of Hurriporo are thus disposed of in the first report under my hand:—

"Lime is here very abundant in the waters, and goitre is said to be common. The water of the new well in the Fort is very inferior, quite unfit for drinking purposes, being loaded with the remains of excrementitious matter."

I turn to the columns of analyses and find that the only notable difference between the two well waters considered "fairly good," and that loaded with the remains of excrementitious matters (No. 3) is in the following particulars.

	1.	2.	3.
Oxygen required for 1000 grs. of water.. . . .	0.00198	0.00193	0.0044
Nitrous acid	Trace.	None.	Present.
Minerals solids grs. per gallon	17.95	20.80	24.50
Chloride of sodium	0.675	1.65	7.05

It is stated that neither of the three contained ammonia or nitric acid. (I pass over items of doubtful accuracy or importance.) The excess of oxygen required for No. 3 is no more than would be caused by 0.1 gr. of nitrous acid.

* On this point I was mistaken. My experiments failed with the apparatus supplied to me for working this new process, but I have since succeeded by the use of apparatus of my own construction. I was also misled to a great extent by the incomprehensible results of some of the examinations made by this method in India, and published. It will, however, be remembered that I gave the results of my experiments with some distrust, and with the announced intention of drawing forth the experience of other analysts on the value of this novel process. I do not regret this in any way, as I succeeded in bringing forward Mr. Harvey's experience; in consequence of which I tried again with proper apparatus, and with good results. Of the practical value of the process I am not yet satisfied; I am still examining that part of the question.

and as the latter is present the evidence of the former drops. We thus find that the remains of excrementitious matters with which the water is said to be loaded, reduce themselves to 0.1 grain of nitrous acid, and a moderate amount of chloride of sodium; both of very natural occurrence in a new well, and affording *per se* not the slightest evidence of sewage contamination, past or present.

Another instance. We are told of Mean Meer that "the whole of the soil is thoroughly saturated with sewage matters; under these circumstances there is little hope of ever procuring drinkable water from any of the wells . . . there is abundant evidence to show that this typhoid fever is almost entirely due to the presence of sewage matters in water and air; . . . it is also believed that diarrhoea and cholera constantly result from the use of impure water;" and it is recommended that all the wells should be filled up. It certainly appears that the water is of unpleasant quality (though on the whole rather superior to that of the seven wells as supplied to the troops at Madras), but from the chemical evidence nothing can be brought in support of the charges of sewage contamination either of soil or of water. The following table gives a summary of the chemical examination of the twenty-six well waters.

	Extreme Quantities.	Average.
Oxygen required per million parts. . . }	0.25 to 1.6	—
Nitrous acid . . .	None in 19, traces in 7	—
Nitric acid. . . .	Traces in 13, none or—in 13	—
Sulphuretted hydrogen	Traces in 24	—
Mineral solids, grains per gallon . . . }	33.4 to 86.2	50
Volatile solids, grains per gallon . . . }	0.45 to 2.94	1
Earthy salts . . .	4.1 to 16.1	7
Chloride of sodium. .	1.4 to 5.5 (1 of 11.5)	3
Sulphate of soda . .	3.8 to 16.4	8
Carbonate of soda . .	12.7 to 59.2	40

These waters appear to be soft and very alkaline (a kind of Vichy water?); the sulphuretted hydrogen is almost certainly caused by decomposition of the alkaline sulphates; it will be remarked, however, that in several waters it is noted as existing along with nitrous acid, a very improbable occurrence, but either of these two substances would deoxidise the permanganate test, lessening considerably any importance that may be attached to the very moderate amount of oxygen said to be consumed by the water. The general absence of nitric acid, and the small amount of chloride of sodium, is strong evidence against sewage contamination. The principal ingredient appears to be carbonate of soda, perhaps the least objectionable saline substance it is possible to have in a water, and certainly not derived from sewage. I look in vain for any evidence in support of the charges; I can only find evidence tending directly to acquit both the soil and the water of the charges laid against them. There is not the slightest doubt that the well waters of ground generally contaminated by sewage show the traces of it most unmistakably, and therefore one, at least, of two things is certain, either that the charges made against the soil and waters of Mean Meer are devoid of foundation, or that the analyses, so called, are worthless. Here is a specimen of what has been done for sanitary science by four years of water analysis under the old system. Is there any guarantee that the new system of analysis will produce better results? No; the causes being the same, the effects will not change.

CORRESPONDENCE.

ESTIMATION OF MANGANESE.

To the Editor of the Chemical News.

SIR,—I have read the article on the "Estimation of Manganese," CHEMICAL NEWS, vol. xxvi., p. 37, contributed

by Mr. Hugo Tamm. That gentlemen seems to have hit on a method of precipitating manganese which is possessed of some advantages, though I hardly think he is the originator of it; for, if I am not mistaken, Mr. Mattieu Williams employed the same reagent in the same manner when chemist at the Atlas Works some years ago. Be this as it may, the precipitation of manganese by ammonium carbonate is certainly complete, provided no free ammonia be present. I cannot say that I have found the precipitate to settle readily, some hours being required for tolerably complete subsidence. Mr. Tamm seems to be very imperfectly acquainted with the practice or literature of manganese estimations, for he apparently imagines the usual process employed to be the precipitation as sulphide, with re-solution and precipitation as carbonate. Upon such a method there can be no doubt the plan proposed is a great improvement, involving as it does but one precipitation instead of two. But has Mr. Tamm never heard of the bromine process, which not only precipitates the manganese in a form fit for weighing, but leaves—what is apparently Mr. Tamm's *bête noire*—the calcium in the filtrate?

It is commonly assumed that the bromine method is not applicable in presence of ammoniacal salts, but this is a mistake, for they seem to present little or no obstruction to its use. Free ammonia is, of course, decomposed by bromine, but the reaction occurs only very slowly in cold and dilute liquids, so that a solution of manganese, made slightly alkaline with ammonia in presence of ammonium salts, is readily and completely precipitated by bromine. As no fixed alkalis are employed, re-solution of the precipitate is quite superfluous.

Interesting as Mr. Hugo Tamm's contributions usually are, I trust he will excuse me if I suggest that they give the reader the impression that his knowledge of standard methods of analysis is derived from a single text-book, and that not a very recent one. Otherwise, it is difficult to understand how he could have been led to describe a process of estimating copper which is found in most works on analysis, the only novelty in his method being the use of ammonium in place of hydrogen sulphite, and ammonium sulphocyanide instead of potassium sulphocyanide. Mr. Tamm has also described a method of precipitating manganese as ammonio-phosphate, a process which originated with Dr. Wolcott Gibbs. But in these days, when analytical processes are published in many journals and several languages, it is next to impossible for those chemists who have not the advantage of a scientific library to keep up with the advance of analytical chemistry, especially in those branches of the subject in which they have no direct and daily interest. But does Mr. Tamm seriously imagine that any analyst worthy of the name is in the habit of separating iron from manganese by means of ammonia, except as a *rough* method of *qualitative* analysis? Mr. Tamm very rightly prefers to separate the iron with succinate of ammonium; but has he really tried this precipitant on the solution of 100 grs. of spiegeleisen, the quantity he recommends for the purpose? If not, let him accept my recommendation to try it, and, when he has filtered and thoroughly washed the iron precipitate, to communicate the result, and any remarks he may desire to make thereon. Every analyst has his pet methods, and those processes are the best to which he is most accustomed; but let me recommend Mr. Tamm to use ammonium acetate for the separation of iron and manganese, precipitating the latter metal from the filtrate by means of bromine, after concentration and addition of enough ammonia to render the liquid slightly alkaline. He can then precipitate any calcium or magnesium from the filtrate in the usual way.

No doubt the precipitation of manganese by ammonium carbonate may prove very useful occasionally, and Mr. Tamm has made a suggestion of considerable value in proposing it as a means of separating manganese from nickel and zinc.

In Sheffield the separation of iron and manganese is

an everyday affair, and I have made many attempts to effect the estimation of manganese in spiegeleisen without first separating the iron. In this I have hitherto been unsuccessful, but am not without hope of ultimate success.—I am, &c.,

ALFRED H. ALLEN.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NORZ. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 5, 1872.

This number contains, in addition to several important papers on meteorology, astronomy, anatomy, and natural history, the following original memoirs relating to chemistry:—

Researches on Alcoholic Fermentation.—Prof. J. Dumas.—This exhaustive essay treats at great length on the much-discussed question of the real nature of fermentation. The eminent *savant* draws the following conclusions from his investigations:—No chemical movement excited in a saccharine liquor can convert sugar into alcohol and carbonic acid; the simple fermentation of a saccharine liquor and yeast may be regulated like any other chemical reaction; the duration of the fermentation is exactly proportionate to the quantity of sugar contained in the liquid; fermentation proceeds more slowly in the dark and *in vacuo*; no oxidation takes place during the fermentation; sulphur is converted into sulphuretted hydrogen by the fermentation; neutral gases do not modify the fermentation-inducing action of yeast; acids, bases, and salts can exercise an accelerating or retarding, disturbing or destructive, action on fermentation, but the accelerating action is more rarely observed; very dilute acids do not affect fermentation, but acids in larger quantity completely destroy it; the same applies to alkalis; carbonated alkalis only impede fermentation when they are present in, or added to, the fermenting liquid in large quantity; earthy carbonates do not interfere with fermentation; neutral salts of potassa and of some other bases exert no influence upon the process; silicate of potassa, borate of soda, soap, sulphites, hyposulphites, neutral tartrate of potassa, and acetate of potassa may be applied for the physiological analysis of ferment and for studying its mode of action.

Ferments Belonging to the Diastase Group.—Prof. J. Dumas.—This paper treats more particularly on the curious action of borax upon yeast, albumenoid substances, synaptase, diastase, myrosine, and malt extract, the salt completely neutralising the known effects of these substances.

Analysis of the Light Emitted by the Phosphorescent Compounds of Uranium.—E. Becquerel.—This exhaustive spectroscopical memoir is illustrated by woodcuts.

Improvement of Wines by Heating them.—Dr. Pasteur.—The contents of this memoir, to which is added a lengthy *procès-verbal* on the results of the investigation of a committee (consisting of wine-growers, wine-merchants, scientific men, and officials of the Ministry of Agriculture) on the subject of wines heated and not heated, chiefly interests wine-growing countries; we may, however, mention that the application of heat tends to improve wines.

Rapid Estimation of Phosphoric Acid, Magnesia, and Lime.—Dr. G. Ville.—Reserved for full translation.

Decolourising Effect of Concentrated Ozone.—A. Houzeau.—It appears that ozone greatly surpasses chlorine in its decolourising effects; this is shown by the action of these substances upon sulphate of indigo and other pigments; the destruction of the indigo is accompanied by the formation of oxygenated water (peroxide of hydrogen).

Some of the Derivatives of Tetrachloride of Naphthalene.—E. Grimaux.—The author describes the following compounds, the modes of preparation of which are recorded at length:—Bichlorated naphthylidene glycol—

a solid crystalline body, slightly soluble in cold water, soluble in about thirty times its weight of boiling water, and readily soluble in alcohol and ether; it fuses at 156°, and yields, with chloride of acetyl, a di-acetate—

a solid crystalline body. With chloride of benzoyl, a dibenzoate is formed—

a substance soluble in alcohol and ether, and fusing at from 148° to 150°. When bichlorated naphthylidene glycol is distilled with hydrochloric acid, there is formed monochlorated naphthol, $\text{C}_{10}\text{H}_7\text{Cl.OH}$, also a solid crystalline body, slightly soluble in cold, more so in boiling, water, and fusing at 109°; when this substance is dissolved in sulphuric acid, the addition of a crystal of oxalic acid produces a violet colour.

Annalen der Physik und Chemie, von Dr. J. C. Poggendorff, No. 6, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

Manometrical Flames.—Dr. R. Kö nig.—This essay, illustrated by woodcuts, treats on acoustics.

Caloric Spectrum of the Sun and of Lime-Light.—S. Lamansky.—A lengthy spectroscopical memoir, illustrated by several engravings.

Experimental Researches on Fluorescences.—E. Hagenbach.—The continuation of an exhaustive monograph on this subject.

Conducting Power of Iron and Argenta for Heat.—H. Weber.—An algebraico-physical essay.

Newly-Contrived Modification in the Construction of Holtz's Influence Machine (Influens-Maschine) Constructed with Discs Rotating in Opposite Directions.—W. Museum.—Illustrated by engravings.

Identity of the so-called Immature Amber with Krantzite.—Dr. H. Spigatis.—The krantzite investigated by the author was of the same consistency as the specimen of immature amber lately found in small quantity in the Balic near the coast, and the krantzite behaves with solvents in the same manner. The specific gravity of the last-named mineral varies from 0.9822 to 0.9845, and its fusion-point was found by the author to be the same as that of the unripe amber, viz., 300°. The chemical composition of both the substances agrees very closely, and succinic acid is found in neither. According to Dana, krantzite is essentially succinite; it occurs in small grains and masses of a light yellow or greenish yellow colour; externally it has a reddish or brownish hue. The formula of krantzite is $\text{C}_{10}\text{H}_{14}\text{O}_4$.

Annales des Mines, No. 2, 1872.

This number contains no original papers relating to chemistry.

Bayerisches Industrie und Gewerbe-Blatt, July, 1872.

Detection of Fatty Oils in Etheral Oils.—F. Rhen.—The process, described and illustrated by woodcuts, essentially consists of a careful process of distillation conducted with a small, but previously weighed or measured, quantity of the essential oil under investigation.

Preparation of Ferricyanide of Potassium.—F. Rhen.—To the cold saturated solution of ferrocyanide of potassium is added a sufficient quantity of rough hydrochloric acid to withdraw 1 atom of potassium from 2 atoms of the salt. There is next gradually added to this mixture a clear solution of hypochlorite of lime (bleaching-powder), until a small quantity of the fluid, tested with perchloride of iron does not indicate the presence of ferrocyanide of potassium; the fluid is then neutralised with chalk, and, lastly, evaporated to crystallisation. The advantages of this process are stated to be—(1) Conversion of the ferro- into ferri-cyanide at the ordinary temperature; (2) only one filtration, and no necessity of washing out a precipitate; (3) nearly the whole of the ferricyanide is obtained by crystallisation, while the last traces may be utilised by means of precipitation with sulphate of iron.

Preparation of Good Lutes and Cements.—Dr. Feichtinger.—This exhaustive memoir treats on—Oil cements; resin cements; glue and gum cements; casein cements; water-glass cements; lime gypsum, pipe-clay, and iron cements.

Annales de Chimie et de Physique, August, 1872.

This number contains the following original papers and essays:—

Researches on the State of Salts when in Solution.—Drs. Berthelot and L. de Saint-Martin.—This monograph is divided into the following sections:—Method and mode of operation; condition of acid salts when in solution; acid salts formed by acetic, benzoic, and polybasic acids; bisuccinates of potassa and ammonia. The general results of these researches may be summarised as follows:—The acid salts formed by monobasic acids do not exist in dilute solution; those formed by polybasic acids become partially decomposed; the quantity decomposed increases gradually, according to the increased dilution of the solution; this quantity continually varies, according to the *rappor*t existing between the neutral salt and the excess of acid, and this variation takes place so that the stability of the acid salt is increased either by the presence of another neutral salt or by the presence of an excess of free acid; division of one base between two acids.

Thermic Researches on Sulphur.—Dr. Berthelot.—The contents of this essay may be summarised as follows:—The conversion of dissolved octahedral sulphur into insoluble sulphur, under the influence of direct sunlight at the ordinary temperature of the air, is accompanied by an evolution of heat equal to about +12.8 cal. to the grm. The conversion of ordinary molten sulphur into insoluble sulphur, at 113°, is also accompanied by an evolution of caloric; this change does not take place by the simple fusion of pure octahedral sulphur, but it occurs under the influence of sunlight.

Oxysulphide of Carbon.—Dr. Berthelot.—Oxysulphide of carbon gas prepared by the action of dilute sulphuric acid upon sulphocyanide of potassium; the formula of this gas is $C_2O_2S_2$. It yields with ammonia a compound, $C_2H_4NS_2O_2NH_4$, carbamate of oxysulphide of ammonia, and, by the withdrawal therefrom of a equivalents of water, this substance yields sulphocyanide of ammonium, and, by the withdrawal of a equivalents of sulphuretted hydrogen, it yields urea, $C_2H_4NS_2NH_2 - H_2S_2 = C_2H_4NO_2$.

Experimental Researches on the Duration of the Electric Spark.—F. Lucas and A. Casin.—This essay, elucidated by engravings, is divided into the following sections:—Principle of the chronoscope lighted by electric sparks; description of apparatus; preliminary experiments; influence of the surface of the condenser; influence of the resistance of the conducting circuit; general formula for expressing the duration of the spark, as indicated by the functions of the three variable exponents, x, y, z .

Freezing of Water.—Prof. Boussingault.—After referring to the old experiments of the Fellows of the Accademia dei Cimento at Florence, and also to the researches of Huyghens (1667), the author records the results of a series of experiments which fully prove that, if the resistance of the sides of the vessel (wherein water is exposed to great cold, the vessel being hermetically sealed) is greater than the expansive force of the act of congelation of the water, the latter remains liquid even at the lowest temperatures to which it is exposed.

Journal für Gasbeleuchtung und Wasserversorgung, No. 8, 1872.

This number contains the following original paper relating to chemistry:—

Influence of Coal-Gas upon Vegetation.—Dr. Virchow.—The author gives a detailed account of a series of experiments made, at the request of the municipal Government of Berlin, by himself and a committee of scientific men, for the purpose of elucidating the question whether the infiltration of coal-gas, in the soil whereupon plants and trees are grown, is or is not injurious to these. The result of the carefully-conducted researches is that coal-gas is an active poison to vegetation, and that trees, shrubs, and ornamental plants are killed by it.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, June 2, 1872.

Deviation of Smoke of Sea-Going Steamers.—Ch. Mène.—The author states that some officers of the Austrian navy have made experiments for causing the smoke arising from the fuel consumed in steam-ships to be discharged under water by the aid of a blowing machine; at the same time a more active and regular combustion is obtained, and the chances of fire on board greatly lessened, while the funnel or iron chimney, one of the most vulnerable parts above deck, is rendered unnecessary. The author has reason to believe that the experiments were in every respect successful.

Improved Safety-Tubes to be Applied instead of Woolf's Tubes.—Ch. Mène.—In a short paper, illustrated with woodcuts, a description is given of a neat contrivance, invented by Alvergnat, Frères, at Paris. The tubes are less liable to breakage and taking up less space than Woolf's.

Action of Sulphuric Acid on Wine.—Dr. L. de Martin.—The author has studied the effect of small quantities (from 1 to 3 grms. of concentrated acid to the hectolitre = 22 gallons) of sulphuric acid upon the process of the fermentation of the must, the result being (1) more rapid and more complete fermentation; (2) a better and more beautiful colour of the wine; (3) analysis did not detect more sulphuric acid in this wine than in samples not so treated, while all the samples had been, as it is termed in Southern France, *plâtrés*, that is to say, treated (cleared) with gypsum. Dr. G. Chancel has repeated these experiments and more thoroughly investigated the process of the fermentation of must, and has found that when the must is alkaline, as it sometimes is, either from some unexplained cause inherent to the juice, or, as is more usually the case, in consequence of much rain, the grapes are spattered and more or less covered with soil. The process of fermentation produces lactic acid instead of alcohol; hence the utility of the sulphuric acid for the purpose of setting up the alcoholic fermentation of the sugar. Dr. Chancel found no increase in the quantity of the sulphuric acid contained in wine so treated. Alcoholic fermentation is not possible in an alkaline fluid, the result in such a case being the formation of lactic acid, formed from the sugar.

American Journal of Pharmacy, August, 1872.

Monobromated Camphor.—Dr. J. M. Maisch.—After referring at some length to the researches of Th. Swart's, Laurent, Perkin, and others, the author describes at great length the results of his experiments made for the purpose of preparing monobromated camphor, which is now largely used medicinally in the United States. The process of preparation is divided into three distinct operations:—(1) the combination of bromine with camphor, bibromide of camphor, which takes place at the ordinary or slightly elevated temperature, particularly in the presence of a trace of alcohol; (2) the formation of the substitution compound, monobromated camphor, which may be effected at a temperature of 100°, or in a much shorter time at 132°; (3) the utilization of the oily residue, a by-product of the first action of bromine upon camphor, the greater part of which is converted into the substitution compound at 260°. Equivalent weights of camphor and bromine are used (the combining weight of camphor, $C_{15}H_{10}O_2$, is 152; that of $2Br = 160$), but in practice one-twelfth more of camphor is advisable. Monobromated camphor crystallises from alcohol

in thin white or colourless prisms or needles; from petroleum-benzine it may be obtained in long flat prisms, which are perfectly transparent and hard. It is insoluble in water, readily soluble in alcohol, ether, and in less than its own weight of hot petroleum-benzine; it is permanent in the air, and not affected by direct sunlight; it fuses at about 67°, and boils, with partial decomposition, at 274°.

Some of the Constituents of the Rhizome of Sanguinaria Canadensis.—E. Peirpoint.—It appears that this drug contains puccin, sanguinarin, and sanguinaric acid; but the quantities of these substances obtained by the author at present are not large enough to admit of a full investigation of their properties and elementary composition, which will form the subject-matter of a future paper.

Disinfection of Sponges.—M. Leriche.—The sponges are first impregnated with a solution of 4 parts of permanganate of potassa in 100 parts of water, and next placed in a solution of 25 parts of sulphurous acid to 100 of water, and finally well washed with water. By this treatment sponges acquire their original condition, and even their marine odour, although they may have been soaked in pus and infectious matter.

Les Mondes, August 8, 1872.

In addition to several original papers and memoirs strictly relating to pharmacy, astronomy, meteorology, agriculture, and medicine, this number contains:—

Petites Annales de Chimie.—Dr. J. Maumené.—The continuation of a monograph on theoretical chemistry, elucidated by a series of algebraic and chemical formulæ.

On some Phenomena observed at Alatri (Italy), and the Effects of Lightning.—Rev. Father A. Secchi, S.J.—The eminent *savant* first gives an account of the difficulties encountered some eight years ago, when a lightning-rod was established on the cathedral and campania of Alatri, buildings which, by their very isolated and elevated position, had often been injured by lightning. The greater portion of this essay is devoted to a minute description of the curious effects of a severe thunderstorm which took place on November 2nd, 1871, and which, while not materially injuring the building alluded to, shows that great care should be taken in the construction of lightning-rods of the proximity of iron gas- and water-mains (underground) comparatively near the spot where the claws of the lightning conductor are placed in the soil.

Bulletin de la Société Chimique de Paris, June 15, 1872.

This number contains the following original papers and memoirs:—

Researches on the Reciprocal Action between some Metals and Iodide of Acetyl.—H. Gal.—The author briefly refers to the researches of Wislicenus and Ponomareff on this subject, and then states that while granulated zinc and small lumps of sodium are very strongly acted upon by iodide of acetyl, this does not take place when tin and mercury are brought into contact with that body; the result of the reaction being the formation of acetic acid, and a small quantity of a liquid heavier than water, and capable of combining with bromine.

Chlorobromide and Chloroiodide of Propylene.—C. Friedel and R. D. Silva.—This essay treats on the best modes of preparation of these bodies, and the reactions they exhibit. The contents of this paper are not, however, well suited for abstraction.

Action of Chloride of Iodine upon Chloroform, upon the Iodides of the Alcohol Radicals, and upon the Action of Bromine upon Chloroform.—C. Friedel and R. D. Silva.—The ultimate result of the action of chloride of iodine upon chloroform, which operation takes place in a sealed tube at from 160° to 170°, is the formation of tetrachloride of carbon, according to the formula $CCl_3H + aClI = CCl_4 + HCl + 1/2 I_2$. It appears, however, that a small quantity of chloroiodide of carbon is also formed. Chloride of iodine acts strongly upon the alcohol radicals, converting these readily into chlorides, iodine being eliminated. By the action of bromine upon chloroform there is formed chlorobromide of carbon, CCl_2Br , a limpid fluid, sp. gr. at 0° = 2.063.

Synthesis of Orcin, and on some Sulphurous Derivatives from Toluene.—G. Vogt and A. Henniger.—The contents of this essay have been already referred to, but the results of the authors' investigations are published in *extenso*.

Preparation of the Salts of Cæsium and Rubidium by means of Lepidolite.—Lecoq de Boisbaudran.—This mineral is acted upon by fluorhydric acid, and the cæsium and rubidium having been separated from the other constituents of the mineral (lepidolite) by well known methods, are isolated by making use of the difference of solubility of the bitartrates of these metals.

La Revue Scientifique de la France et de l'Etranger, August 3, 1872.

This number contains no original papers relating to chemistry, but we quote the titles of the following important memoirs:—

Development of Submarine Telegraphy.—E. Saigey.

Constitution and Movements of Glaciers.—Ch. Grad.

August 10, 1872.

This number contains no original papers relating to chemistry. We call attention to the following lecture:—

Vegetable Products.—Dr. G. Ville.—The continuation of the author's discourses on practical agriculture in the experimental field near Vincennes.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents,
54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1044. W. R. Lake, Southampton Buildings, London, "Improvements in the manufacture of pulp from vegetable fibres for making paper and other materials."—A communication from G. Swift, San Francisco, California, U.S.A.—Petition recorded April 8, 1872.
2261. W. E. Gill, Salisbury Street, Strand, W.C., "Improvements in treating vegetable juices, and in the apparatus and materials to be employed therefor."
2262. T. R. Crampton, Great George Street, Westminster, "Improvements in the manufacture of gas and fuel, and in apparatus to be used for this purpose."
2265. A. M. Clark, Chancery Lane, "Improvements in the manufacture of phosphoric acid and acid phosphate of lime, and the applications of the same."—A communication from L. H. Blanchard, Paris.—Petition recorded July 27, 1872.
2277. E. P. H. Vaughan, F.C.S., Chancery Lane, "Improvements in the treatment of phosphates of lime."—A communication from A. Striedter, Paris.
2279. J. Brown, Edinburgh, "Improvements in the treatment of sewage and in the manufacturing of manures."
2282. G. Haseltine, Southampton Buildings, London, "An improved process of converting cast-iron into steel."—A communication from T. H. Alexander, Washington, U.S.A.—Petitions recorded July 30, 1872.
2287. P. A. Dormoy and F. A. Paget, Adelphi, W.C., "Improvements in puddling furnaces."—Petition recorded July 31, 1872.

NOTICES TO PROCEED.

865. J. Werner, Mannheim, Baden, "An improved composition to be used as a substitute for 'brewers' pitch' for lining vats, casks, and tubs, and for other like purposes."—Petition recorded March 21, 1872.
908. G. J. Snelus, Dowlaia, Glamorganshire, "An improved lining for cupola furnaces, also applicable to the formation of the beds of reverberatory furnaces."—Petition recorded March 25, 1872.
943. A. Beveridge, Leith, N.B., "Improvements in preparing, cleansing, and refining animal fats, and in the means and apparatus employed therefor."—A communication from A. Jurgens, Oss, North Brabant, Holland.—Petition recorded March 30, 1872.
971. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in liqueurs or cordials and other beverages, and in apparatus to be employed in their manufacture."—A communication from F. A. Joannon, Paris.
979. W. R. Lake, Southampton Buildings, London, "An improved compound for cleansing carpets and other woven fabrics."—A communication from L. Stern, Boston, Mass., U.S.A.—Petitions recorded April 9, 1872.
1051. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in the treatment of animal and vegetable substances."—A communication from W. Adamson, Philadelphia, Penn., U.S.A.—Petition recorded April 9, 1872.
1376. D. G. Fitzgerald, Brixton, Surrey, and B. C. Molloy, of Elm Court, Temple, Middlesex, "Improvements in heating compound substances by the agency of electricity, and thereby decomposing them or resolving them into their components, and in apparatus employed therein."—Petition recorded May 6, 1872.
2006. G. Noble, Woodford Bridge, Essex, "Improvements in the method of treating various kinds of fibrous materials for the manufacture of writing, printing, and other paper."—Petition recorded July 3, 1872.
2156. F. J. Cheesbrough, Liverpool, "Improvements in evaporating and concentrating sulphuric and other acids, also salt, sulphur, and other substances capable of evaporation, and in the apparatus to be used therein."—A communication from W. T. Clough, Newark, Essex, New Jersey, U.S.A.—Petition recorded July 18, 1872.
2286. G. Thom, Chorley, Lancashire, and J. Stenhouse, Pentonville, London, "Improvements in treating fatty substances containing colouring matters, and in obtaining useful products therefrom."—Petition recorded July 22, 1872.
2293. G. T. Bousfield, Sutton, Surrey, "Improvements in furnaces for deoxidising iron ores preparatory to their being worked into wrought-iron."—A communication from J. Wilson, Dover, New Jersey, U.S.A.—Petition recorded July 29, 1872.

PATENTS SEALED.

425. R. F. Smith, Glasgow, N.B., "Improvements in obtaining yellow and red prussiates."
429. W. Ireland, Macclesfield, Cheshire, and J. Ireland, Manchester, "Improvements in the manufacture of cast or Bessemer steel ingots."—A communication from R. Pink, Hoerde, Westphalia.—Dated February 10, 1872.
454. F. H. Warlich, Camberwell, Surrey, "Improvements in the manufacture of artificial fuel, and in apparatus to be used for this purpose."—Dated February 13, 1872.
606. S. T. Vanel, Paris, "A new composition and process for waterproofing all sorts of tissues, linen, paper, and other materials."—Dated February 26, 1872.
752. E. Watten, Middlesboro'-on-Tees, Yorkshire, "Improvements in explosive compounds."—A communication from A. de Terré, and E. de Mercader, Liège, Belgium.—Dated March 12, 1872.
1080. J. J. Bodmer, Hammermith, Middlesex, "Improvements in the manufacture of iron and steel."—Dated April 11, 1872.

1409. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in the treatment of ores, more particularly iron ore, for the manufacture of cast-iron, wrought-iron, and steel therefrom, and in the apparatus to be employed therein."—A communication from La Société Metallurgique pour l'Exploitation des Procédés Ponsard, Paris.—Dated May 8, 1872.
1799. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in the manufacture of iron."—A communication from W. Sellers, Philadelphia, Penn., U.S.A.
1801. G. Haseltine, Southampton Buildings, London, "Improvements in the manufacture of iron and steel, and in apparatus employed therefor."—A communication from J. W. Middleton, Philadelphia, Penn., U.S.A.—Dated June 14, 1872.
1837. T. Hampton, Ickles, near Rotherham, Yorkshire, "Improvements in the manufacture of Bessemer steel ingots."—Dated June 18, 1872.

NOTES AND QUERIES.

Pure Aluminum.—Can your readers inform me of an easy way by which I could procure pure aluminum in the laboratory as an experiment?—E. PURDON.

Lamp for Water Oven.—Can any of your readers inform me of the best sort of lamp to use for a water-oven? I cannot get gas, and spirit of wine is too expensive, as I sometimes keep it going all night, and common oil makes a black mess with the soot that forms.—ALISON.

Powerful Galvanic Battery.—In Mr. Highton's description of a Powerful Galvanic Battery, I do not understand the instructions with respect to the arrangement for the "negative." Should feel obliged if Mr. Highton, or some of your readers, would give a little further explanation on the subject.—H. HARGREAVES.

Powerful Galvanic Battery.—Would Mr. Highton kindly give practical working directions for the construction of the battery described by him, and add information on the following points:—(1) Resistance compared with Grove or Bunsen; (2) comparative tendency to polarisation; (3) constancy and duration of action?—R. T. C.

Hydrocyanate of Morphia, &c.—(1). What is the best plan for making a true hydrocyanate of morphia? I have reason to fear that the hydrocyanate of morphia of Dr. J. M. Maisch (CHEMICAL NEWS, vol. xxiii., p. 310) is nothing but pure morphia. (2). Does the hydrocyanate of bismuth exist; if so, how is it obtained? (3). What is the best method to preserve meat by means of carbolic acid instead of common salt?—J. H. L. SCHUMANN, Muraysburg, Colony of the Cape of Good Hope.

Test for Pure Anthracen.—Can you or any of your readers give a simple and reliable test for the quantity of pure anthracen in a commercial sample of crude? I find those at present in use, viz., alcohol, methylated spirit, and bisulphide of carbon, all the latter especially, dissolve a considerable portion of the anthracen, thereby causing the result to be very unsatisfactory. Now that this article has some commercial importance, an easily applied test, and one that would be free from doubt, is of considerable importance to tar distillers.—D. G.

Detection of Turmeric in Mustard.—In an article on the "Detection of Adulteration" in the "English Mechanic" of the 9th inst., Mr. A. H. Allen describes the following improved modification of the boric acid test for turmeric:—"Shake half a teaspoonful of the mustard in the cold with two or three times its bulk of methylated spirits. Filter the solution, and evaporate the liquid to dryness at a steam heat in a porcelain basin, in which is placed a piece of filter-paper about the size of a penny. When all the alcohol has been driven off, moisten the paper with a strong aqueous solution of boric acid, and again evaporate completely. In presence of turmeric the paper will acquire a reddish colour; but, as a further proof, drop on it some solution of caustic potash or soda, which will produce a very beautiful series of colours, in which green and purple are most evident. On then adding hydrochloric acid, a red colour will be produced, which can be again turned green and blue by addition of excess of alkali. The colours are very vivid and characteristic, pure mustard giving no such result. . . . Gambooge may be detected in the same way as turmeric, but gives a bright red instead of a green or blue colour on treatment with caustic soda, and on adding excess of hydrochloric acid the paper becomes merely yellow instead of the orange-red colour produced in presence of turmeric."

TO CORRESPONDENTS.

- Y. Cox.—Received, with thanks.
W. F. D.—You will find the original description in *Comptes Rendus*, January 15, 1872, and *Journal de Pharmacie et de Chimie*, March, 1872.
Mediocrity.—(1). Cannot say. (2). No. (3). Enquire at the British Museum. (4). Very little. (5). Cannot say.

THE CHEMICAL NEWS.

VOL. XXVI. No. 665.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

BRIGHTON MEETING, AUGUST 14, 1872.

INAUGURAL ADDRESS OF THE PRESIDENT,

WILLIAM B. CARPENTER, M.D., LL.D., F.R.S.,

Registrar of the University of London.

(Concluded from p. 77).

AND now, having studied the working action of the human intellect in the scientific interpretation of Nature; we shall examine the general character of its products; and the first of these with which we shall deal is our conception of *matter* and of its relation to *force*.

The psychologist of the present day views matter entirely through the light of his own consciousness: his idea of matter in the abstract being that it is a "something" which has a permanent power of exciting sensations; his idea of any "property" of matter being the mental representation of some kind of sensory impression he has received from it; and his idea of any particular kind of matter being the representation of the whole aggregate of the sense-perceptions which its presence has called up in his mind. Thus, when I press my hand against this table, I recognise its unyieldingness through the conjoint medium of my sense of touch, my muscular sense, and my mental sense of effort, to which it will be convenient to give the general designation of the *tactile* sense; and I attribute to that table a *hardness* which resists the effort I make to press my hand into its substance, whilst I also recognise the fact that the force I have employed is not sufficient to move its mass. But I press my hand against a lump of dough; and finding that its substance yields under my pressure, I call it *soft*. Or again, I press my hand against this desk; and I find that, although I do not thereby change its *form*, I change its *place*; and so I get the *tactile* idea of *motion*. Again, by the impressions received through the same sensorial apparatus, when I lift this book in my hand, I am led to attach to it the notion of *weight*, or *ponderosity*; and by lifting different solids of about the same size, I am enabled, by the different degrees of exertion I find myself obliged to make in order to sustain them, to distinguish some of them as *light*, and others as *heavy*. Through the medium of another set of sense-perceptions, which some regard as belonging to a different category, we distinguish between bodies that *feel* "hot" and those that *feel* "cold;" and in this manner we arrive at the notion of differences of temperature. And it is through the medium of our *tactile* sense, without any aid from vision, that we first gain the idea of *solid form*, or the three dimensions of space.

Again, by the extension of our *tactile* experiences, we acquire the notion of *liquids*, as forms of matter yielding readily to pressure, but possessing a sensible weight which may equal that of solids: and of *air*, whose resisting power is much slighter, and whose weight is so small that it can only be made sensible by artificial means. Thus, then, we arrive at the notions of *resistance* and of *weight* as properties common to all forms of matter; and now that we have got rid of that idea of light and heat, electricity and magnetism, as "imponderable fluids," which used to vex our souls in our scientific childhood, and of

which the popular term "electric fluid" is a "survival," we accept these properties as affording the practical distinction between the "material" and the "immaterial."

Turning, now, to that other great portal of sensation, the sight, through which we receive most of the messages sent to us from the universe around, we recognise the same truth. Thus it is agreed alike by physicists and physiologists, that *colour* does not exist *as such* in the object itself, which has merely the power of reflecting or transmitting a certain number of millions of undulations in a second; and these only produce that affection of our consciousness which we call colour, when they fall upon the retina of the living percipient. And if there be that defect, either in the retina or in the apparatus behind it, which we call "colour-blindness" or Daltonism, some particular hues cannot be distinguished, or there may even be no power of distinguishing any colour whatever. If we were all like Dalton, we should see no difference, except in form, between ripe cherries hanging on a tree, and the green leaves around them; if we were all affected with the severest form of colour-blindness, the fair face of Nature would be seen by us as in the *chiaroscuro* of an engraving of one of Turner's landscapes, not as in the glowing hues of the wondrous picture itself. And in regard to our visual conceptions, it may be stated with perfect certainty, as the result of very numerous observations made upon persons who have acquired sight for the first time, that these do *not* serve for the recognition even of those objects with which the individual had become most familiar through the touch, until the two sets of sense-perceptions have been co-ordinated by experience.*

When once this co-ordination has been effected, however, the composite perception of form which we derive from the visual sense alone is so complete, that we seldom require to fall back upon the touch for any further information respecting that quality of the object. So, again, while it is from the co-ordination of the two dissimilar pictures formed by any solid or projecting object upon our two retinæ, that (as Sir Charles Wheatstone's admirable investigations have shown) we ordinarily derive through the sight alone a correct notion of its *solid* form, there is adequate evidence that this notion, also, is a mental judgment based on the experience we have acquired in early infancy by the consentaneous exercise of the visual and *tactile* senses.

Take, again, the case of those wonderful instruments by which our visual range is extended almost into the infinity of space, or into the infinity of minuteness. It is the mental, not the bodily eye, that takes cognisance of what the telescope and the microscope reveal to us. For we should have no well-grounded confidence in their revelations as to the *unknown*, if we had not first acquired experience in distinguishing the true from the false by applying them to *known* objects; and every interpretation of what we see through their instrumentality is a *mental judgment* as to the probable form, size, and movement of bodies removed by either their distance or their minuteness from being cognosed by our sense of touch.

The case is still stronger in regard to that last addition to our scientific *armamentum*, which promises to be not inferior in value either to the telescope or the microscope; for it may be truly said of the spectroscope, that it has not merely extended the range of our vision, but has almost given us a new sense, by enabling us to recognise distinctive properties in the chemical elements which were previously quite unknown. And who shall now say that we know all that is to be known as to any form of matter; or that the science of the *fourth* quarter of this century

* Thus, in a recently recorded case in which sight was impaired by operation to a young woman who had been blind from birth, but who had nevertheless learned to work well with her needle, when the pair of scissors she had been accustomed to use was placed before her, though she described their shape, colour, and glistening metallic character, she was utterly unable to recognise them as scissors until she put her finger on them, when she at once named them, laughing at her own stupidity (as she called it) in not having made them out before.

may not furnish us with as great an enlargement of our knowledge of its properties, and of our power of recognising them, as that of its *third* has done?

But, it may be said, is not this view of the material universe open to the imputation that it is "evolved out of the depths of our own consciousness"—a projection of our own intellect into what surrounds us—an *ideal* rather than a *real* world? If all we know of matter be an "intellectual conception," how are we to distinguish this from such as we form in our dreams?—for these, as our laureate no less happily than philosophically expresses it, are "true while they last." Here our "common sense" comes to the rescue. We "awake, and behold it was a dream." Every healthy mind is conscious of the difference between his waking and his dreaming experiences; or, if he is now and then puzzled to answer the question "Did this really happen, or did I dream it?" the perplexity arises from the consciousness that it *might* have happened. And every healthy mind, finding its own experiences of its waking state, not only self-consistent, but consistent with the experiences of others, accepts them as the basis of his beliefs, in preference to even the most vivid recollections of his dreams.

The lunatic pauper who regards himself as a king, the asylum in which he is confined as a palace of regal splendour, and his keepers as obsequious attendants, is so "possessed" by the conception framed by his disordered intellect, that he *does* project it out of himself into his surroundings; his refusal to admit the corrective teaching of common sense being the very essence of his malady. And there are not a few persons abroad in the world who equally resist the teachings of educated common sense whenever they run counter to their own preconceptions; and who may be regarded as—in so far—as affected with what I once heard Mr. Carlyle pithily characterise as "diluted insanity."

It has been asserted, over and over again, of late years, by a class of men who claim to be the only true interpreters of Nature, that we know nothing but matter and the laws of matter, and that force is a mere fiction of the imagination. May it not be affirmed, on the other hand, that while our notion of *matter* is a conception of the intellect, *force* is that of which we have the *most direct*—perhaps even the *only direct*—cognisance? As I have already shown you, the knowledge of resistance and of weight which we gain through our tactile sense is derived from our own perception of *exertion*; and in vision, as in hearing, it is the force with which the undulations strike the sensitive surface, that affects our consciousness with sights or sounds. True it is that in our visual and auditory sensations, we do not, as in our tactile, *directly* cognosce the force which produces them; but the physicist has no difficulty in making sensible to us indirectly the undulations by which sound is propagated, and in proving to our intellect that the force concerned in the transmission of light is really enormous.*

It seems strange that those who make the loudest appeal to experience as the basis of all knowledge should thus disregard the most constant, the most fundamental, the most direct of all experiences; as to which the common sense of mankind affords a guiding light much clearer than any that can be seen through the dust of philosophical discussion. For, as Sir John Herschel most truly remarked, the universal consciousness of mankind is as much in accord in regard to the existence of a real and intimate connection between cause and effect, as it is in regard to the existence of an external world; and that consciousness arises to every one out of his own sense of *personal exertion* in the origination of changes by his individual agency.

Now, while fully accepting the logical definition of cause as the "antecedent or concurrence of antecedents on which the effect is invariably and unconditionally consequent," we can always single out one *dynamical antecedent*—the power which does the work—from the

aggregate of *material conditions* under which that power may be distributed and applied. No doubt the term cause is very loosely employed in popular phraseology; often (as Mr. Mill has shown) to designate the occurrence that immediately preceded the effect;—as when it is said that the spark which falls into a barrel of gunpowder is the cause of its explosion, or that the slipping of a man's foot off the rung of a ladder is the cause of his fall. But even a very slightly trained intelligence can distinguish the power which acts in each case, from the conditions under which it acts. The force which produces the explosion is locked up (as it were) in the powder; and ignition merely liberates it, by bringing about new chemical combinations. The fall of the man from the ladder is due to the gravity which was equally pulling him down while he rested on it; and the loss of support, either by the slipping of his foot, or by the breaking of the rung, is merely that change in the material conditions which gives the power a new action.

Many of you have doubtless viewed with admiring interest that truly wonderful work of human design, the Walter printing machine. You first examine it at rest; presently comes a man who simply pulls a handle towards him; and the whole inert mechanism becomes instinct with life, the blank paper continuously rolling off the cylinder at one end, being delivered at the other, without any intermediate human agency, as large sheets of print, at the rate of 15,000 in an hour. Now what is the *cause* of this most marvellous effect? Surely it lies essentially in the power or force which the pulling of the handle brought to bear on the machine from some extraneous source of power,—which we in this instance know to be a steam-engine on the other side of the wall. This force it is which, distributed through the various parts of the mechanism, really performs the action of which each is the instrument; *they* only supply the vehicle for its transmission and application. The man comes again, pushes the handle in the opposite direction, detaches the machine from the steam-engine, and the whole comes to a stand; and so it remains, like an inanimate corpse, until recalled to activity by the renewal of its moving power.

But, say the reasoners who deny that force is anything else than a fiction of the imagination, the revolving shaft of the steam-engine is "matter in motion;" and when the connection is established between that shaft and the one that drives the machine, the *motion* is communicated from the former to the latter, and thence distributed to the several parts of the mechanism. This account of the operation is just what an observer might give who had looked on with entire ignorance of everything but what his eyes could see; the moment he puts his hand upon any part of the machinery, and tries to stop its motion, he takes as direct cognisance, through his sense of the effort required to resist it, of the *force* which produces that motion, as he does through his *eye* of the motion itself.

Now, since it is universally admitted that our notion of the external world would be not only incomplete, but erroneous, if our visual perceptions were not supplemented by our tactile, so, as it seems to me, our interpretation of the phenomena of the universe must be very inadequate, if we do not mentally co-ordinate the idea of force with that of motion, and recognise it as the "efficient cause" of those phenomena,—the "material conditions" constituting (to use the old scholastic term) only "their formal cause." And I lay the greater stress on this point, because the mechanical philosophy of the present day tends more and more to express itself in terms of *motion* rather than in terms of *force*;—to become *kinetics* instead of *dynamics*.

Thus, from whatever side we look at this question,—whether the common sense of mankind, the logical analysis of the relation between cause and effect, or the study of the working of our own intellects in the interpretation of Nature,—we seem led to the same conclusion; that the notion of *force* is one of those elementary forms of thought with which we can no more dispense than we can with

* See Sir John Herschel's "Familiar Letters on Scientific Subjects."

the notion of space or of succession. And I shall now, in the last place, endeavour to show you that it is the substitution of the dynamical for the mere phenomenal idea, which gives their highest value to our conceptions of that order of Nature which is worshipped as itself a god by the class of interpreters whose doctrine I call in question.

The most illustrative, as well as the most illustrious, example of the difference between the mere generalisation of phenomena and the dynamical conception that applies to them, is furnished by the contrast between the so-called laws of planetary motion discovered by the persevering ingenuity of Kepler, and the interpretation of that motion given us by the profound insight of Newton. Kepler's three laws were nothing more than comprehensive statements of certain groups of phenomena determined by observation. The *first*, that of the revolution of the planets in elliptical orbits, was based on the study of the observed places of Mars alone; it might or might not be true of the other planets; for so far as Kepler knew, there was no reason why the orbits of some of them may not be the excentric circles which he had first supposed that of Mars to be. So Kepler's *second* law of the passage of the Radius Vector over equal areas in equal times, so long as it was simply a generalisation of facts in the case of that one planet, carried with it no reason for its applicability to other cases, except that which it might derive from his erroneous conception of a whirling force. And his *third* law was in like manner simply an expression of a certain harmonic relation which he had discovered between the times and the distances of the planets, having no more rational value than any other of his numerous hypotheses.

Now the Newtonian "laws" are often spoken of as if they were merely *higher generalisations* in which Kepler's are included; to me they seem to possess an altogether different character. For starting with the conception of two *forces*, one of them tending to produce continuous uniform motion in a straight line, the other tending to produce a uniformly accelerated motion towards a fixed point, Newton's wonderful mastery of geometrical reasoning enabled him to show that, if these *dynamical* assumptions be granted, Kepler's *phenomenal* "laws," being necessary consequences of them, must be *universally* true. And while that demonstration would have been alone sufficient to give him an imperishable renown, it was his still greater glory to divine that the fall of the moon towards the earth—that is, the deflection of her path from a tangential line to an ellipse—is a *phenomenon of the same order* as the fall of a stone to the ground; and thus to show the applicability to the entire universe, of those simple dynamical conceptions which constitute the basis of the Geometry of the Principia.

Thus, then, whilst no "law" which is simply a *generalisation of phenomena* can be considered as having any *coercive* action, we may assign that value to laws which express the *universal conditions of the action of a force*, the existence of which we learn from the testimony of our own consciousness. The assurance we feel that the attraction of gravitation *must* act under all circumstances according to its one simple law, is of a very different order from that which we have in regard (for example) to the laws of chemical attraction, which are as yet only generalisations of phenomena. And yet even in that strong assurance, we are required by examination of the basis on which it rests, to admit a *reserve of the possibility* of something different; a reserve which we may well believe that Newton himself must have entertained.

A most valuable lesson as to the allowance we ought always to make for the unknown "possibilities of nature," is taught us by an exceptional phenomenon so familiar that it does not attract the notice it has a right to claim. Next to the law of the universal attraction of masses of matter, there is none that has a wider range than that of the *expansion of bodies by heat*. Excluding water and one or two other substances, the fact of such expansion might be said to be *invariable*; and, as regards bodies whose gaseous condition is known, the law of expansion can be

stated in a form no less simple and definite than the law of gravitation. Supposing those exceptions, then, to be unknown, the law would be *universal* in its range. But it comes to be discovered that water, whilst conforming to it in its expansion from $39\frac{1}{2}^{\circ}$ *upwards* to its boiling-point, as also, when it passes into steam, to the special law of expansion of vapours, is exceptional in its *expansion* also from $39\frac{1}{2}^{\circ}$ *downwards* to its freezing-point; and of this failure in the universality of the law no *rational* can be given. Still more strange is it, that by dissolving a little *salt* in water, we should remove this exceptional peculiarity; for *sea-water* continues to contract from $39\frac{1}{2}^{\circ}$ downwards to its freezing-point 12° or 14° lower, just as it does with reduction of temperature at higher ranges.

Thus from our study of the mode in which we arrive at those conceptions of the orderly sequence observable in the phenomena of Nature which we call "Laws," we are led to the conclusion that they are human conceptions, subject to human fallibility; and that they *may* or *may not* express the ideas of the great Author of Nature. To set up these laws as self-acting, and as either excluding or rendering unnecessary the power which alone can give them effect, appears to me as arrogant as it is unphilosophical. To speak of any law as "regulating" or "governing" phenomena, is only permissible on the assumption that the law is the expression of the *modus operandi* of a governing power.—I was once in a great city which for two days was in the hands of a lawless mob. Magisterial authority was suspended by timidity and doubt; the force at its command was paralysed by want of resolute direction. The "laws" were on the statute book, but there was no power to enforce them. And so the powers of evil did their terrible work; and fire and rapine continued to destroy life and property without check, until new power came in, when the reign of law was restored.

And thus we are led to the culminating point of man's intellectual interpretation of Nature,—his recognition of the unity of the Power, of which her phenomena are the diversified manifestations. Towards this point all scientific inquiry now tends. The convertibility of the physical forces, the correlation of these with the vital, and the intimacy of that *nexus* between mental and bodily activity, which, explain it as we may, cannot be denied, all lead upward towards one and the same conclusion; and the pyramid of which that philosophical conclusion is the apex, has its foundation in the primitive instincts of humanity.

By our own remote progenitors, as by the untutored savage of the present day, every change in which human agency was not apparent was referred to a particular animating intelligence. And thus they attributed not only the movements of the heavenly bodies, but all the phenomena of Nature each to its own Deity. These Deities were invested with more than human power; but they were also supposed capable of human passions, and subject to human capriciousness. As the uniformities of nature came to be more distinctly recognised, some of these Deities were invested with a dominant control, while others were supposed to be their subordinate ministers. A serene majesty was attributed to the greater gods who sit above the clouds; whilst their inferiors might "come down to earth in the likeness of men." With the growth of the scientific study of Nature, the conception of its harmony and unity gained ever-increasing strength. And so among the most enlightened of the Greek and Roman philosophers, we find a distinct recognition of the idea of the unity of the directing mind from which the order of Nature proceeds; for they obviously believed that, as our modern poet has expressed it,—

"All are but parts of one stupendous whole,
Whose body Nature is, and God the Soul."

The science of modern times, however, has taken a more special direction. Fixing its attention exclusively on the *order* of Nature, it has separated itself wholly from theology, whose function it is to seek after its *Cause*. In

this, science is fully justified, alike by the entire independence of its objects, and by the historical fact that it has been continually hampered and impeded in its search for the truth as it is in Nature, by the restraints which Theologians have attempted to impose upon its inquiries. But when science, passing beyond its own limits, assumes to take the place of theology, and sets up its own conception of the *order* of Nature as a sufficient account of its *cause*, it is invading a province of thought to which it has no claim, and not unreasonably provokes the hostility of those who ought to be its best friends.

For whilst the deep-seated instincts of humanity, and the profoundest researches of philosophy, alike point to mind as the one and only source of power, it is the high prerogative of science to demonstrate the *unity* of the power which is operating through the limitless extent and variety of the universe, and to trace its *continuity* through the vast series of ages that have been occupied in its evolution.

ON THE
COLLECTION AND ANALYSIS FOR GASEOUS
CONSTITUENTS OF SAMPLES OF DEEP
SEA-WATER.*

By W. LANT CARPENTER, B.A., B.Sc., F.C.S.

THIS paper was a summary of the author's experience on this subject in the "Porcupine" expeditions of 1869 and 1870. Many of the descriptions of apparatus employed, and of the conclusions from long series of analyses of 1869, had appeared in the *Proceedings of the Royal Society* for 1870. The analyses made in the summer of 1870 tended to confirm, in most points, those of 1869, and showed in addition that both surface and bottom waters contained more carbonic acid and less oxygen in the more southern than in the more northern latitudes. The examinations extended from the latitude of the Faroe Isles to that of Lisbon.

The main object of the paper, however, was to show that, contrary to the general supposition on the subject, there was no greater quantity of dissolved gaseous constituents in the bottom than in the surface water; and the author supported his position (which was generally accepted in the discussion which followed) by his own observations, and also by theoretical arguments, against such supposed excess, especially enquiring where the source of it was, while he fully admitted the power of the pressure at great depths to retain it in solution if it once were evolved there.

ON THE
PRESENCE OF ALBUMEN IN NEUTRAL FATS,
AND A
NEW METHOD OF OBTAINING STEARIC
AND PALMITIC ACIDS.*

By W. LANT CARPENTER, B.A., B.Sc., F.C.S.,

IN the International Exhibition of 1871 there were exhibited several specimens of stearic acid, &c., by Professor J. C. A. Bock, of Copenhagen. It was stated that they were produced by a new process, which possessed very many advantages over any other known method. The author of this paper, having twice visited Copenhagen to study the

process, and having extended its application to neutral fats other than tallow, in England, thought that an account of the scientific aspects of it might not be uninteresting to members of the Section. The inventor, Professor and State Councillor Bock, of Copenhagen, was by profession a medical man, formerly attached to the Danish Court, and a man of high culture and education, though but little known in England. He had been led up to his invention by patient microscopical and chemical study of the properties of neutral fats, and reflection upon the reasons of the disadvantages of methods hitherto practised. These disadvantages Mr. Carpenter pointed out at some length in his paper. Hitherto, when fats were decomposed by alkali, a considerable excess of alkali above the theoretical quantity was required, unless the operation were conducted under very great pressure, when the risk of explosion was great. When they were decomposed by sulphuric (or any other strong) acid, as was usually the case in England, much of the fat was lost by being charred and burnt, and the remainder was so black that it was necessary to distil it to render it good enough in colour for manufacturing purposes. The risk of fire, and of explosion in this operation was considerable, and the expense great. Professor Bock had shown that most neutral fats were made up of minute globules of fat, surrounded by albuminous envelopes, which form 1 to 1.5 per cent of the weight of the fat, and he considered that the excess of alkali, of pressure, or of heat required to decompose fats, was really used in the destruction and removal of these albuminous envelopes, which also attracted to themselves the colouring matters contained in the fat, or produced therein during its decomposition. The existence of the albumen could be demonstrated in the laboratory by dissolving the fat in ether or benzol, and precipitating the solution by water, or by boiling the fat on a *strong* solution of oxalic acid. In both cases the albuminous envelopes collected at the plane of junction of the two liquids. In Professor Bock's process the albuminous envelopes were broken and partly destroyed by the action, for a limited time, and at a given temperature, of a small quantity of strong sulphuric acid. The neutral fat then poured out from the envelopes in a state ready for decomposition by water in open tanks, an operation which required several hours for its complete performance. Its progress was judged of by microscopical examination of the crystals of the fat, or fatty acid, conformed by slowly cooling a thin layer upon a glass slip. When it was completed, the glycerine, which was dissolved in the water used for the decomposition, was drawn off, purified, and concentrated for sale. The fatty acids, amounting to 94 per cent of the original fat, were at this stage of a very brown or blackish colour. The next operation was to eliminate the albuminous envelopes, and with them most of the colouring matters. This was done by submitting the fatty acids in open tanks to the action of dilute solutions of certain oxidising agents, by which the black matters were partly oxidised, and their specific gravity greatly increased, so that when the oxidation had proceeded far enough they readily subsided to the bottom of the tank, leaving the fatty acids comparatively good in colour.* After two or three washings with dilute acid and water, the fatty acids were cold pressed and hot pressed in the usual way, and the result was a stearic acid higher in melting-point and greater in quantity than could be produced in any other way, and an oleic acid excellently fitted for the manufacture of soap and other purposes. One of the greatest advantages of the process was, that all operations were conducted in open tanks, boiled with steam not exceeding 35 lbs. pressure.

Mr. CARPENTER stated that he was at present engaged in applying this process to palm oil and other vegetable fats, and he illustrated his paper with specimens of the various stages of manufacture.

* The oxidising agents that had been employed were—the three strong mineral acids, sulphuric, nitric, and hydrochloric, permanganate and bichromate of potash and hypochlorite of lime.

PURE WROUGHT-IRON.

It has hitherto been deemed impossible to make pure wrought-iron; this has recently been done on a large commercial scale at the Bowling Iron-Works, Bradford, by the Henderson process. The analysis of the pig-iron used is—

Graphitic carbon	3.155
Combined carbon	0.581
Silicon	1.646
Sulphur	0.070
Phosphorus	0.635
Manganese	1.472
Iron	92.644

100.203

The wrought-iron from the above analyses—

	Per cent.
Carbon	0.272
Silicon	none
Sulphur	the barest trace
Phosphorus	none
Manganese	none
Iron, by direct determination ..	99.500

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.*

By Dr. F. GRACE CALVERT, F.R.S.

(Continued from p. 67.)

I SHALL now call your attention to three commercial preparations of indigo, obtained by the action of sulphuric acid on it. The first is called *sulpho-purpuric acid* or *phenicine*, which is made by adding 1 part of indigo to 4 parts of highly concentrated sulphuric acid, heating for a short time, varying from half-an-hour to an hour, or until a small quantity of it mixed with a large quantity of water gives a deep purple colour. Great care must be bestowed on this part of the operation, so as to avoid the formation of a compound, to which I shall have again to call your attention, *sulpho-indigotic acid*. The acid mass produced is thrown into about 40 or 50 parts of water, when a beautiful purple precipitate is produced, which is collected on a filter, and slightly washed with weak muriatic acid. To dye wool with this sulpho-purpuric acid it is necessary to add to the bath a little muriatic acid, when it yields to the wool a fine dark purple-blue, that can be converted into various shades of purple by passing the wool so dyed in a bath containing a small quantity of carbonate or acetate of soda, which removes a small quantity of sulpho-indigotic acid that may be present, and gives rise to *sulpho-purpurate of soda*, which is a faster dye than the acid itself.

Sulpho-indigotic Acid is manufactured by dissolving 1 part of indigo in 10 or 12 parts of concentrated sulphuric acid, and heating the whole at a temperature of 120° F. very carefully for some hours. The operation is completed when a small quantity dissolves entirely in cold water.

The acids above described, when obtained perfectly pure, have the following formulæ:—Sulpho-purpuric acid, $C_{16}H_{10}N_4O_2SO_3$; sulpho-indigotic acid, $C_8H_5NO_3SO_3$.

Berzelius admits a third compound, called *hypo-sulpho indigotic acid*. These acids are transformed into neutral salts of soda, and sold under the names of neutral paste and carmine of indigo. They are prepared by neutralising the sulpho-acids with carbonate of soda, and the

paste so formed is thrown on a wooden filter to remove the sulphate of soda which it contains, as well as a green colouring-matter, which is doubtless modified chlorophyll. The paste is then washed with a solution of chloride of sodium. It is a curious fact that carmines of indigo, which are perfectly soluble in pure water, are altogether insoluble in water containing either sulphate of soda or chloride of sodium.

Whilst speaking of the sulpho-indigotates, it may be useful to notice that the sulpho-indigotates of potash and soda are soluble in 100 to 150 parts of water, the sulpho-indigotates of lime, magnesia, and alumina are freely soluble, whilst those of baryta and lead are insoluble.

The carmines of indigo are especially used by silk-dyers, in consequence of the removal of the green colouring-matter above referred to, and which, if allowed to remain, would spoil the blue or purple which they wish to obtain. The method practically adopted to ascertain if the sample has been well washed, consists in rubbing a small quantity of it on a piece of glazed paper, which, when the colour dries, gives a colour varying from a pale blue to a rich copper purple, according to the mode of manufacture; and if any green colouring-matter is left in, it shows itself as a green ring round the blue circle.

The following may be taken as the composition of a sample of carmine of indigo of fair quality:—

Water	85.0
Indigo	10.2
Saline residue	4.8

100.0

The sulpho-indigotic acids are especially used by woollen dyers, who add to the dye-beck a little alum and cream of tartar, which helps the fixing of the indigo on the wool. The green colouring-matter is in this case not objectionable, having no affinity for the fibre of wool.

The carmines of indigo, as well as the sulpho-acids, are easily decolourised by reducing agents, such as hydrogen and sulphuretted hydrogen, but they gradually reassume their original colour when exposed to the atmosphere, through the absorption of oxygen.

The above compounds, not being suitable for dyeing cotton, and not giving colours on silk and wool that may be considered fast, I shall now proceed to describe a few of the methods followed to obtain fast indigo blues. They are all based on the principle of the reduction of blue indigo into white indigo. The latter compound is held in solution by an alkali, which enables the dyer or printer to introduce it into the fibre of the fabric, where, on exposure to the atmosphere, the alkali combines with carbonic acid, and the white indigo thus liberated absorbs oxygen, and becomes insoluble blue indigo. The principal class of goods to which this chemical reaction is applied is to the vegetable fibres, linen, and especially cotton. As far as dyeing is concerned, the processes can be classed under two heads, hot and cold. The hot process is principally applied to wool, the cold to vegetable fibres, especially cotton.

The oldest and still most generally employed method of preparing cold vats, consists of putting into a vat containing about 2000 gallons of water, 60 lbs. of indigo, very finely powdered, 180 lbs. of slaked lime, and 120 lbs. of sulphate of protoxide of iron or green vitrol (free from any trace of copper salt), the two latter substances being added from time to time. The greater part of the lime used unites with the sulphuric acid of the iron salt, to produce sulphate of lime or gypsum, and the liberated protoxide of iron removes the oxygen from the indigo, becoming converted into saline oxide, whilst the reduced indigo dissolves in the excess of lime employed.

Messrs. R. Schloesser and Co., of Manchester, have introduced within the last year or two a marked improvement in the preparation of cold vats, which removes the great objections of the bulky precipitate of

* The Cantor Lectures, delivered before the Society of Arts. Revised and communicated by the Author.

sulphate of lime, the formation of an oxide of iron, and the loss of indigo by its combination with the oxide of iron referred to in the previous part of the lecture. The bath remaining much more fluid, the pieces are less apt to be spotted, and a better class of work is produced. To carry out their process, they add to the ordinary 2000 gallon vat 20 lbs. of ground indigo, 30 lbs. of iron borings, 30 lbs. of their remarkable powdered zinc, and 35 lbs. of quick-lime; the whole is stirred up from time to time for 24 hours, when it is ready for use. If the bath is not considered sufficiently strong, a little more lime and zinc are introduced.

The chemical theory of the process is, that the zinc, under the influence of the lime, decomposes water, combining with its oxygen, and the hydrogen thus liberated, removes oxygen from the indigo, which then dissolves in the lime.

To dye cotton yarn in the above vats, it is simply necessary to dip it for a few minutes in the dye-bath, and expose it to the atmosphere, when the green hue it has acquired passes rapidly into blue. This operation is repeated until the yarn has attained the required depth of shade, when it is passed into weak vitriol, washed, and is ready for market.

To dye calicoes, the pieces are hooked on frames, passed through a bath of weak milk of lime, and then dipped into the reduced indigo vat. After fifteen minutes, the frame is taken out, and the cloth exposed to the air for about the same length of time. It is again dipped, the process being repeated until the required depth of tint is attained. It is then passed through weak vitriol, and washed. The cold vats are especially used when it is wished to obtain white and yellow designs on a blue ground; but when the object in view is to produce a self-colour, a more rapid process is adopted. This consists in passing the pieces through a dye-beck, then through an acid liquor, and lastly in water, by means of rollers fixed in the vat. The bath is composed of lime, sulphate of iron, and indigo, but is kept hot, instead of cold as in the former case.

There is still another process, which is now used to a limited extent only, but was at one time very extensively employed. It produces on the cloth a pale blue which has a great similarity of tint to that seen on the china porcelain, from which it derives its name of china-blue. To produce it the pieces are printed with a mixture containing very finely-powdered indigo, and a little acetate of iron, and are made to pass through six successive vats. The first two contain lime, the third sulphate of iron, the fourth a solution of caustic soda, the fifth a dilute solution of sulphuric acid, and the sixth water. When the design has acquired the required depth of blue, the pieces are washed, passed once more through weak sulphuric acid, and again washed. The chemical reactions are exactly similar to those in the cold vat process.

For dyeing wool, a modification of the old woad vat is employed. The use of woad being now almost entirely discontinued, I shall merely call your attention to the process in which indigo has been substituted for woad. It bears the name of Indian vat, doubtless from the process having been practised in India and imported from thence. It is as follows:—8 lbs. of powdered indigo is added to a bath containing 3½ lbs. of bran, 3½ lbs. of madder, and 12 lbs. of potash, which is maintained for several hours at a temperature of 200° F. It is then allowed to cool to 100° F., when fermentation ensues. After about 48 hours, the indigo is rendered soluble, being reduced, by the decomposition of the sugar and other products contained in the bran and the madder-root during the process of fermentation. The bath should have a greenish yellow appearance, having a frothy scum of a blue coppery hue.

Of late years, improvements have been made in this class of vats, by which the expense of using madder is avoided. They are now prepared by adding to water, at a temperature of 200° F., 20 buckets of bran, 26 lbs. of soda crystals, 12 lbs. of indigo, and 5 lbs. of slaked lime.

After 5 hours, the bath is allowed to cool to 100° F., when fermentation ensues, and the indigo is dissolved in the alkali. The management of these vats require great experience and care, for if the fermentation is too slow, the indigo is not properly reduced, whilst if too active large quantities of indigo may be lost. The researches of Dr. Schunck, already referred to, not only show the method of avoiding this loss, but explain why it occurs. The remarks which I made as to the causes of failure in the manufacture of indigo are applicable here, namely, that if the fermentation becomes alcoholic and acetic, the non-oxidisable indigo compounds described by Dr. Schunck are generated.

I cannot leave the subject of indigo without bringing before you a most curious source of its production, namely, the human body. Medical men had observed from time to time that urine, secreted under certain pathological conditions, became brown, and sometimes even blue, when exposed to the atmosphere. The late Dr. Hassel discovered that in some instances the colouring matter was indigo, but here, again, we are indebted to Dr. Schunck for much information on the subject. In three papers presented to the Royal Society, he has proved that urine, in cases similar to those examined by Dr. Hassel, contained the glucoside of indigo, or indican. He also observed that indican was a very frequent constituent of urine secreted by persons in a healthy state, and, in fact, that it is produced generally when persons do not take sufficient exercise, and he has on several occasions succeeded in producing it by taking in his food a rather large excess of sugar.

(To be continued).

ON THE EVIL EFFECTS OF THE USE OF ARSENIC IN CERTAIN GREEN COLOURS.*

By FRANK W. DRAPER, M.D.

(Continued from p. 34).

BUT in studying the reported cases of wall-paper poisoning, we need not confine our selections to observations made in other countries. Abundant testimony is afforded in our own midst; and this fact, that the pernicious effects of using the arsenical paper-hangings have been recognised and experienced here, and that cases have repeatedly occurred demonstrating the susceptibility and exposure of our own people, is of obvious importance and possesses a value which investigations at a distance could hardly be thought to have in comparison. The following are some of the instances which have been observed in this community:—

A well-marked case of poisoning occurred in 1863 in Boston, and was reported by Dr. W. E. Rice. The patient was a woman aged seventy-five years. After living a few days in a room which had had been papered with a bright green paper, she was attacked with a burning sensation in the throat and stomach, with frequent, though slight, vomiting after taking food. She had diarrhoea, with some dysenteric discharges; there was also great weakness, with trembling of the limbs and loss of appetite. Subsequently, severe cramps came on in the stomach and bowels; the skin was clammy; the voice was altered; pulse 100; bowels constipated; abdomen very tender on pressure. There was violent retching and vomiting on taking small quantities of either liquid or solid food. All these symptoms were much aggravated after sweeping or dusting the room. Proper treatment alleviated the distress; but when the room was again dusted, the symptoms recurred with renewed violence. The residence of the patient was now changed, and recovery followed. The paper was found,

* From the "Third Annual Report of the State Board of Health of Massachusetts."

on examination, to contain arsenite of copper in its pigment.*

The notes of the following case were communicated to the writer by the individual who is the subject of the report:—In the autumn of 1859, a middle-aged lady, the wife of an eminent citizen of Boston, commenced to occupy a room which had been freshly decorated with wall-paper whose pattern consisted of alternate stripes of gilt and green flock; of the poisonous character of the latter she was wholly unaware. Excepting a neuralgia from which she had long suffered, she considered her health at this time to be perfect. Soon after beginning to habitually sit in the apartment she noticed a change in her feelings. The neuralgia, which previously had been only annoying, became intensified. She had headache and vertigo. There was nausea and distressing vomiting. The appetite was impaired; there was a dry cough and a bad taste in the mouth. Marked emaciation was manifest, and an almost intolerable sense of prostration and exhaustion ensued. All these symptoms compelled her to keep the room the more continuously. Remedies were meanwhile applied unavailingly, since the cause of the ailment was not detected. In the following summer, a stay of several months in the country was attended with distinct relief; but a return to the town residence was followed by a renewal of the painful experience, and during the winter months, while the room was occupied, the patient suffered distressingly. A second summer's absence brought a second season of respite, only to be followed by a third attack which renewedly baffled the skill of the attending physician. The symptoms at this period were of the most aggravated character. Frequent attacks of fainting, intense paroxysms of neuralgia, dizziness, almost incessant vomiting, and great prostration reduced the patient to the last extremity, and her life was despaired of. At this time, when the sufferer was almost moribund, it occurred to herself that the possible cause of all her deplorable state was in the green paper of her room. A sample was at once analysed by Dr. A. A. Hayes, and was pronounced by him to be "loaded with arsenic and extremely unsafe." From this discovery was dated the beginning of the patient's recovery. The paper was removed as soon as possible, but so fully had the patient's system become charged with the poison, and so depressing were its primary effects, that the consequences of the renewed infection are experienced to this day.

The colouring matter of the paper had become so loosely adherent that, on passing the hand or a cloth lightly over its surface, a distinct green stain was left. The workman who removed the paper from the walls was made seriously ill, although precautions were taken to prevent that accident; and it was ascertained also that the paper-hanger who had originally applied the paper was similarly poisoned.

Cases might be multiplied almost indefinitely; but it is believed that those which have been cited will suffice to demonstrate the fact that very harmful effects may and do result from the employment of an agent whose poisonous character is well recognised and whose sole recommendation by those who offer it displayed on the paper-hangings which are designed to decorate our walls is that it produces an attractive colour cheaply. These recorded instances exhibit a series of symptoms which, upon analysis, clearly show that the arsenical poisoning impresses itself on the human system locally as well as through its general influence. The local effects are precisely such as would be expected from the continued inhalation of an irritant agent, or from its presence in the atmosphere; the dryness of the throat and mouth, the inflammation of the mucous surface of the eye, the occasional salivation, the husky and altered voice, the severe frontal headache (about the frontal sinuses), the nausea and vomiting, the dry cough, all point to the action more or less marked and immediate on the various surfaces with which the poison comes in contact; while the more prolonged and insidious influence

is indicated in the great debility and lassitude, the emaciation, the impaired nervous power, the irritability of disposition and depression of spirits, the muscular trembling, the occasional convulsions, the vertigo, the chilled extremities, the restless sleep, the pale cachectic aspect, the digestive disturbances, and the neuralgia, which comprise the general or constitutional symptoms. It is, of course, obvious that all these phenomena will not manifest themselves in the same individual as the results of exposure; nor will they present the uniformity which characterises other modes of poisoning. Of those in any degree affected, probably the majority would remark only the more primary and insignificant symptoms; for example, after a night's sleep in an apartment with the arsenical paper on its walls, the individual will notice a headache or a dryness of the mouth. It is only after prolonged exposure, or in persons specially susceptible, that the more serious effects are manifested. Thus it is by a careful criticism of the various symptoms presented in a given case, and by observing the fact that in the presence of the assumed cause no other cause can be discovered sufficient to account for these various local and constitutional symptoms, that we are enabled to arrive at definite conclusions. There are no distinct and characteristic effects which will allow the observer at once to discriminate such a case, as salivation enables him to do in mercurial poisoning, or as the blue line of the gums and wrist-drop, in poisoning by lead. It is, indeed, this very obscurity and want of uniformity characterising the effects of chronic arsenical poisoning from the cause in question that has led many writers to question, and not a few to deny, the possibility of the dependence of such a condition on this exposure. It will doubtless also explain the fact that comparatively few of these instances are recognised in their true and independent relation, and are reported as such; for it is plain that only the most unequivocal cases would be likely to see the light through the journals, and we are justified in inferring that a very great number of instances have occurred which, from their anomalous character, have escaped detection.

This feature is of evident importance as affecting the public health. If cases were habitually occurring presenting well-defined signs, and readily traced to their cause, the community would entertain no doubt concerning the course to be followed, and arsenical paper-hangings would very quickly become unfashionable. But the individual instances, like some of those cited, are in many respects perplexing and obscure, readily eluding the tact of the physician in his attempts to determine their true character, and baffling him in the application of his remedies; hence there is a vantage ground for scepticism on the one hand, and for ignorance on the other.

In this connection, it may be observed that the symptoms due to poisoning by arsenical paper-hangings are, notwithstanding the peculiarities above alluded to, strikingly similar to and, in many respects, absolutely identical with, those of chronic arsenical poisoning when the agent, swallowed in small and frequently repeated doses, exerts its cumulative action. These latter symptoms are notoriously varied in character and present many apparent anomalies. They follow little regularity of manifestation. In different individuals, they are exhibited sometimes with most emphasis in the digestive system, sometimes in the nervous system, and sometimes the influence is a general one and shows itself in a complication of symptoms. Thus it will be seen to be unnecessary to define a distinct train of phenomena as peculiar to poisoning by green wall-paper, since these offer no points of essential difference from those observed in ordinary chronic arsenical poisoning. The difference is one of degree, and depends on the more or less prolonged and continuous exposure to small amounts of the poison introduced into the system slowly and by indirect channels.

Although the fact that serious and sometimes very alarming disease follows, in certain cases, the use of arsenical-green wall-paper is of more consequence to the

* *Boston Med. and Surg. Journ.*, vol. lxi. (1863), p. 297.

community at large than any discussion of hypotheses concerning the method of infection, this latter question is not without interest. Various theories have been advanced to explain the processes by which the poisonous pigment enters the system so as to produce its manifold pernicious effects. Gmelin, who first called attention to the subject in any of its relations, was of the opinion that the poison was absorbed as a volatile gas, the product of a "fermentation of the organic matters with which the arsenic is mixed." A little later, M. Louyet, of Brussels, declared that this gaseous exhalation was a special form of arseniuretted hydrogen, and based his theory on the observation that, when a mixture of arsenic and distilled water is allowed to stand a few days, the water at the end of that time gives out a distinct odour of garlic, which, as is well known, is characteristic of arsenic; and this evolution he thinks due to a decomposition of the water in the presence of arsenic. Analogously, the moisture which is almost always present in the walls of rooms undergoes a similar decomposition, evolving a volatile and very poisonous product. This view he thought strengthened by the presence of the alliaceous odour in rooms papered with the arsenical hangings. Basedow, a Prussian chemist of distinction, published similar opinions, the source of danger being attributed by him to the development, under the influence of moisture, of a certain amount of arseniuretted hydrogen. Other observers have adopted similar views, advocating the theory of gaseous decomposition, either from the presence of moisture,* or from slow combustion ("eremacausis") of the organic elements contained in the paper or its pigment,† or from the presence in the room of illuminating gas which escapes in small amount and reacts on the arsenite of copper to produce arseniuretted hydrogen.‡

All these theories of the evolution of a poisonous gas are to be distinguished from the absolutely untenable notion which was at one time accepted popularly, viz., that the poisoning took place by the inhalation of volatile arsenical fumes which escaped from the paper. This idea is obviously fallacious, since arsenic is volatilised and evolves "fumes" at a temperature of 360° F., 150° above the boiling-point of water.

These hypotheses are not accepted by the majority of chemists at the present day. It is the general belief that the poison escapes from the paper into the atmosphere in the form of dust, mechanically disengaged. This view seems not unreasonable in consideration of the composition of the paper and of the methods employed to engage the pigment in position. The connection between the paper and its colour, at the beginning depending only on the adhesiveness of size, certainly does not grow stronger with age. The paper is applied to the wall when moist with the paste or glue of the paper-hanger, and the size surrenders in this process something of its adhesive property. Varying states of the atmosphere, as they regard moisture and dryness, still farther carry on the change by which, with alternate drying and wetting, the pigment is less and less securely held. So that any mechanical violence, however small,—the action of drafts of air, or the passing of a duster, or vibration,—serves to disengage an impalpable powder containing the poisonous agent. It is well known that in the most unused room the air contains a certain amount of dust, so that a single sunbeam let into such a room when it is darkened reveals a perfect cloud of flying particles whose origin no one can tell. It is easy to see how the loosely adherent arsenical powder on the wall-paper of such a room may constitute a part of this dust, and the atmosphere become charged in greater or less degree with the pernicious agent. One element in the vexed problem of the relation of dust and disease thus finds solution.

This view has received confirmation in the fact that the dust resting on the furniture and mantels of such rooms has been tested, and has been found to contain the arsenic in considerable amount.

* Otto Mohr.

† John Taylor.

‡ C. T. Jackson.

A third class of observers, including M. Kirchgässer, of Coblenz, and M. Chevallier, accept both these theories and allow a dual toxic influence. They admit all that is claimed for the dust hypothesis, but believe also, in view of the occasional detection of the odour of garlic or of mustiness in the suspected rooms, that under certain conditions of moisture a gas is generated, poisonous in character, which escapes to infect the air.

(To be continued.)

CORRESPONDENCE.

THE BRITISH ASSOCIATION AND THE MECHANICAL EQUIVALENCE OF HEAT.

To the Editor of the Chemical News.

SIR,—In 1870, the British Association paid £50 for experiments on the mechanical equivalence of heat. In 1871, a committee was re-appointed to examine and report on the subject.

The reports, &c., of the Sections were presented to-day, but this committee have made no sign. Surely they ought, in justice, to say what they have done, or what they have not done; what conclusions they have come to, or not come to; to make some statement or other. Section A refused last year to allow me to say anything on the subject: the committee will do nothing for themselves.

It is a very important subject, and it is unjust to stifle it. It seems to me clear that the doctrines enunciated by Professor Tait in his Thermodynamics must, to say the least, be much modified. Why not acknowledge it? I see that Dr. Maxwell, in his very recently published treatise "On Heat," has very much modified or explained away Tait's theory of the absolute zero of temperature.—I am, &c.,

H. HIGHTON.

Brighton, August 15, 1872.

MISCELLANEOUS.

British Association for the Advancement of Science.

—The following is a complete list of the papers which were brought before Section B (Chemical Science) at the Brighton meeting, under the presidency of Dr. Gladstone, F.R.S., &c. They will be published, in full or in abstract, according to their importance, in the CHEMICAL NEWS.

The President's Address.

Report of the Committee for Investigating the Chemical Constitution and Optical Properties of Essential Oils used for Perfumes.

Prof. J. W. Mallet.—On the Fusion of Metallic Arsenic.

Prof. J. W. Mallet.—On the effect upon Meteoric Iron as regards the capability of being Forged, of previous heating to redness or whiteness, *in vacuo*.

W. Chandler Roberts.—On a Curve, Illustrating the British Gold Coinage.

W. Lant Carpenter.—On the mode of Collection of Samples of Deep Sea-Water, and of their Analysis for Dissolved Gaseous Constituents.

T. E. Thorpe.—On a New Filter-Pump.

Dr. Moffat.—On the Tube Ozonometer.

C. J. Woodward.—On a Modification of Hofmann's Apparatus for the Electrolysis of Water.

Preliminary Report of the Committee on Siemens's Electrical Resistance Pyrometer.

Report of the Committee for Superintending the Monthly Reports of the Progress of Chemistry.

Dr. Gladstone and Mr. Tribe.—On the Mutual Helpfulness of Chemical Affinity, Electricity, and Heat in the Decomposition of Water.

- J. Dewar.**—On Specific Heats at High Temperatures.
J. W. Mallet.—On the Occurrence of Native Sulphuric Acid in Texas.
J. W. Mallet.—On the Occurrence in recent Pine Timber of Fichtelite, a hydrocarbon hitherto only known in a fossil state.
W. Weldon.—On the Manufacture of Chlorine by Manganoite of Magnesium.
F. C. Calvert.—On the Composition of Bleaching-Powder.
A. Tribe.—On the Precipitation of Silver by Copper.
G. Gladstone.—On the Dust thrown up by Vesuvius in the Recent Eruption.
Dr. Schenk.—On the Amounts of Heat required to Raise Elementary Bodies from the Absolute Zero to their State of Fusion.
W. Lant Carpenter.—On the Presence of Albumen in Neutral Fats, and on a New Process for the Manufacture of Stearic and Palmitic Acids.
J. F. Walker.—On Dinitrobenzene.
C. R. A. Wright.—On New Derivatives from Morphine and Codeine.
J. Williams.—Preliminary Note on the Preparation of Gavanine.
J. A. Wanklyn.—On some New Methods of Analysing the Ethers.
Rev. H. Highton.—On a Powerful Galvanic Battery.
Prof. Crum Brown.—On Chemical Nomenclature.
Dr. T. Wood.—On the Teaching of Elementary Chemistry.
Dr. Gladstone.—On Filiform Native Silver.
G. Unwin.—To Exhibit Specimens of Agate and other forms of Natural Colloid Silica.
J. A. Wanklyn.—On the Continuous Production of Oxygen.
J. B. Grantham.—Report on the Utilisation of Sewage.
W. J. Cooper.—On a Proposed Method of Preventing the Fermentation of Sewage. (Discussion on the Report on the Utilisation of Sewage.)
Herr von Rath.—The Crystallographic System of Leucite.
Dr. Ord.—Crystallisation of Salts in Colloid Solutions.
Dr. Oppenheim.—The Action of Phosphorus on Alkaline Solutions of Metals.
John Galletly.—Ignition of Cotton by Saturation with Fatty Oils.
James Howell.—On the Minerals lately Found in the Drainage Works at Brighton. (With Specimens.)

OFFICERS AND COMMITTEE.

- President.**—Dr. J. Hall Gladstone, F.R.S., F.C.S.
Vice-Presidents.—F. A. Abel, F.R.S.; Professor Williamson, F.R.S.; J. H. Gilbert, Ph.D., F.R.S.; S^r Benjamin Brodie, Bart., F.R.S.; Prof. G. C. Foster, F.R.S.
Secretaries.—Dr. Mills; W. Chandler Roberts, F.C.S.; Dr. W. J. Russell, F.R.S.; T. Wood, Ph.D.
Committee.—J. Attfield, Ph.D.; H. B. Brady, F.L.S.; W. Lant Carpenter, B.A., B.Sc.; M. Carteighe; H. Deane, F.L.S.; J. Dewar, F.R.S.E.; J. Baker Edwards, Ph.D., D.C.L.; G. Gladstone, F.R.G.S.; J. P. Gassiot, D.C.L., F.R.S.; D. Hanbury, F.R.S.; W. E. Heathfield, F.R.S.E.; G. D. Longstaff, M.D.; J. W. Mallet, Ph.D.; A. F. Marocco; H. Matthews; W. H. Perkin, F.R.S.; B. H. Paul, Ph.D.; G. F. Rodwell, F.R.A.S.; G. F. Schacht; W. W. Stoddart, F.G.S.; F. Sutton; J. Smyth, M.A.; T. E. Thorpe, F.R.S.E.; A. Tribe; J. Williams; C. R. A. Wright, D.Sc.

Place of Meeting for Next Year.—The meeting next year will be held at Bradford, commencing on September 19. **President Elect**—Dr. James P. Joule, LL.D., D.C.L., F.R.S. Belfast has been selected for the meeting of 1874.

University of London—First B.Sc. and Preliminary Scientific (M.B.) Examinations.—The following are among those who presented themselves for the Examinations for Honours:—*Mathematics and Mechanical Philosophy*.—First Class. J. M. Lightwood, First B.A. (Exhibition), Trinity Hall, Cambridge; R. H. Jude, First B.Sc.,

Christ's College, Cambridge. Second Class. J. F. Main, First B.Sc., private study. *Chemistry*.—First Class. R. E. Carrington, Prel. Sci. (Exhibition), Guy's Hospital; B. A. Whitelegge, Prel. Sci., University College. Second Class. H. B. Briggs, Prel. Sci., King's College; H. D. Stewart, Prel. Sci., King's College; R. H. Jude, First B.Sc. and Prel. Sci., Christ's College, Cambridge; F. Goodchild, Prel. Sci., Epsom and University Colleges; A. S. Napier, First B.Sc., Owens College; W. B. Worthington, First B.Sc. and Prel. Sci., Owens College. *Organic Chemistry, and Materia Medica and Pharmaceutical Chemistry*.—First Class. W. B. Houghton (Exhibition and Gold Medal), University College; H. R. Crocker (Gold Medal), University College; P. T. Duncan, University College. Second Class. A. P. Gould, University College; G. E. Herman, London Hospital.

Fluorescence.—At the meeting of the American Institute, President Henry Morton, of the Stevens Institute of Technology, read a paper on "Fluorescence," or that action by which rays of the higher purple, or even invisible light, such as produce most strongly photographic action, excite in certain bodies lower rates of vibration, resulting in the emission of light, generally of a red, green, or clear blue colour. This paper was illustrated by a number of striking experiments. Thus, a flask of solution of chlorophyll (a green colouring-matter obtained from leaves), which is of an olive-green colour, being held in a beam of blue light proceeding from a "vertical lantern" appeared to be full of a blood-red liquid. Various solutions colourless in ordinary light were then shown to exhibit the brightest hues when illuminated by the violet rays of the lantern, or those obtained from the electrical discharge of the Professor's large coil in rarefied gases. The speaker then announced that in the course of the examination which he had been making of such substances, he had encountered one which he believed to be as yet unknown, and which possessed the property of developing light by fluorescence in a pre-eminent degree. This body was obtained from petroleum, and he would propose to take for it the name "Viridin." The word viridin had been already applied as a synonym for chlorophyll, but was now practically obsolete, and too appropriate to the present substance to be thrown away. A large drawing of a flower, with leaves painted seemingly in light umber tints, was then shown and illuminated by electric discharges, when it appeared of the most vivid green. The peculiar fluorescent spectrum of this body, and its relations to the spectra of other substances, was explained, and many other illustrations were exhibited.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Stances de l'Academie des Sciences, August 12, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

Mode of Division of One Base between Several Monobasic Acids when together in Aqueous Solution.—Dr. Berthelot.—A physico-chemical essay elucidated by several tables exhibiting results of experiments and theoretical calculations.

Conversion of Dextro-Rotating Tartaric Acid into Racemic Acid.—E. Jungfleisch.—The main gist of this essay is that optically active, or dextro-rotating tartaric acid is, when heated along with water in sealed tubes to 175°, converted almost entirely into racemic

acid. The author has made this experiment on a large scale in a Papin pot made of wrought steel, and enamelled inside, and found that the result is the same when the vessel is carefully heated in an oil-bath up to 180°.

Although not strictly belonging to chemistry, we quote the title of the following memoir:—

Report on the Carboniferous Flora of the Département de la Loire.—M. Grand Eury.—This exhaustive paper is an important contribution to our knowledge of the plants which have been converted into coal.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 14, 1872.

This number contains the following original memoirs and papers:—

Bromated Chlor-Salicylic Acid and Bromated Chlorobenzoic Acid.—A. Claus.—After briefly referring to the researches of Drs. Beilstein, Kuhlberg, and Pfeiffer on this subject, the author states that the best method of obtaining the bromated compound of these acids is to treat their silver salts with bromine. The bromated chlor-salicylic acid is a solid crystalline body, fusing at 151°, and subliming, without decomposition, at 160°. 1 part of this acid is soluble in 380 parts of water at 21°; most of its salts are also freely soluble in water. The formula is $C_7H_4Br_2ClO_4$. Bromated chlorobenzoic acid is also a solid, crystalline body, more difficultly soluble in water than the former acid (1 part requires, at 0°, 2840, and at 21°, 1080 parts of water for solution); at 160°, this substance also sublimes without decomposition. In the preparation of chlorobenzoic acid from benzoic acid and a mixture of chlorate of potassa and hydrochloric acid a large quantity of dichlorobenzoic acid is formed.

Thio-Isopropyl Alcohol and Isopropyl-Sulphonic Acid.—A. Claus.—After describing at great length the mode of preparation of thio-isopropyl alcohol, it is stated that that substance is a fluid lighter than water, soluble in every proportion in alcohol and ether, and not quite insoluble in water, from which solution the mercury combination of the alcohol is obtained upon the addition of mercuric chloride. Concentrated nitric acid decomposes thio-isopropyl alcohol with violence; but with dilute nitric acid the reaction is moderate, and attended for a few moments by a very brilliant purplish colouration, which disappears, the result of the reaction being the formation of sulphuric acid and a new organic acid. The formula of thio-isopropyl alcohol is C_3H_7S . Isopropyl-sulphonic acid, $C_3H_7SO_3H$, is the new organic acid alluded to, and a solid crystalline body fusing at below 100°, forming crystalline salts.

Synthesis of Sulphuretted (Geschwefelte) Tannic Acids.—H. Schiff.—Notwithstanding its intrinsic merits, the contents of this lengthy essay, elucidated by a large number of complex formulæ, are not well suited for useful abstraction, an observation also applying to the following paper.

Constitution of Coumarine.—H. Schiff.

Mesoxalic Acid.—J. Ossikovsky and G. Barbaglia.—The authors tried in vain to obtain free mesoxalic acid, by first converting chloro-oxalic acid ethyl-ether into a cyanogen compound, and next saponifying that body. Every experiment made to convert the cyanogen compound into COOH failed. The authors describe the mode of preparing acetyl-oxamic acid ethyl-ether, a solid crystalline substance, per centually consisting of—C, 45.28; H, 5.66; N, 8.74. When boiled with water this body is decomposed.

Contribution to our Knowledge on Guanidin.—J. Ossikovsky.—The preparation of guanidin according to Bannow's method, viz., treatment of iodide of cyanogen with three times its weight of alcoholic ammonia solution at 10 per cent in sealed tubes at 100°, does not, according to the author, give quite satisfactory results, only a small quantity of guanidin being obtained after purifying the crude product. By taking up, under the influence of either boiling dilute sulphuric acid or of alkalis, the elements of water, guanidin is split up, yielding first urea and ammonia; the former is again converted into carbonic acid and ammonia by taking up water.

New Method of the Formation of Amides and Nitriles.—E. A. Letts.—This excellent and exhaustive monograph is divided into the following sections:—Action of acetic acid upon sulpho-cyanide of potassium; action of isobutyric acid upon sulphocyanide of potassium; action, respectively, of valerianic, benzoic, cumic, and cinnamic acids upon sulphocyanide of potassium.

Dimethyl-Anthracen.—A. van Dorp.—The author describes, at length, the synthetic preparation of dimethyl-anthracen, by treating xylyl-chloride with water at a high temperature in a sealed tube. By that operation an oily body is obtained which, when it is passed through red-hot tubes filled with pumice-stone, is converted into dimethyl-anthracen. This material is very like anthracen, and fuses at 200°; when dissolved in glacial acetic acid and oxidised by chromic acid, an oxidation product is obtained which is at present the subject of the author's research.

Crystalline Shape of Hydrate of Chloral.—P. Groth.—A strictly crystallographical memoir.

Contribution to our Knowledge of the Aromatic Addition Products.—C. Graebe.—This monograph is divided into the following sections:—Introduction, containing a general review of the compounds obtained by the addition of hydrogen to the aromatic compounds; naphthalin-tetrahydride, $C_{10}H_{12}$; cymen, $C_{10}H_{16}$; reduction of cymol.

Diphenyl.—G. Schultz.—This paper contains the preliminary account of some results of researches undertaken with the view of ascertaining more correctly the constitution of the aromatic hydro-

carbons. The author treats on the preparation and oxidation of diphenyl, on monobrom-diphenyl, oxidation of dibrom-diphenyl, and on reduction of diphenyl.

Some of the Derivatives of Benzyl-Toluol.—Th. Zincke.—This essay treats on—(1) the action of bromine upon benzyl-toluol, $C_6H_5-CH_2-CH_2-C_6H_5$; (2) action of nitric acid, di-nitro-benzyl-toluol, $C_{14}H_{13}(NO_2)_2$; (3) nitro-methyl-benzophenon, $C_{14}H_9(NO_2)-CO-CH_2-C_6H_5$, or—

(4) tetra-nitrobenzyl-toluol, $C_{14}H_5(NO_2)_4$; (5) action of fuming sulphuric acid, benzyl-toluol-disulphic acid, $C_{14}H_{13}(SO_3H)_2$, and the salts of that acid.

Benzyl-Ethyl-Benzol.—J. T. Walker.—This body—

the mode of preparation of which is described at length, is a colourless liquid, exhibiting a faintly aromatic odour; sp. gr. at 18.9°, 0.985; readily soluble in alcohol, ether, and chloroform; boils at from 294° to 295°. By oxidation, this hydrocarbon (consisting, in 100 parts, of—C, 91.84; H, 8.16) yields benzyl-benzoic acid.

Benzyl-Sulpho Acid.—G. Barbaglia.—This memoir treats on the preparation of benzyl-sulpho acid by means of the oxidation of the sulphur compounds of benzyl.

Some of the Derivatives of Benzylamine.—J. Strakosch.—This essay is divided into the following sections:—Introduction, treating on monamines in general, and on the best modes of preparation of benzylamine; cyanbenzylamine; action of chlorocyan upon benzylamine; cyanbenzylamine; tribenzyl-melamine; dibenzyl-guanidin; dibenzyl-sulpho-urea; benzyl-acetamide; nitrobenzyl-mercaptan; nitrobenzyl-sulphide.

Observations on Isobutyl-Aldehyde.—A. Pfeiffer.—In the first part of this essay the preparation of the isobutyl-aldehyde is described at length. In pure state, this substance is a colourless, strongly refrangible liquid, which yields with ammonia a rather difficultly crystallising compound. Isobutyraldin is, in crude state, an amorphous solid mass, which, however, may be obtained in crystalline state by repeated treatment with ether. Carbo-isobutyraldin, $C_4H_8N_2S_2$, obtained by treating isobutyl-aldehyde with sulphide of carbon, is a solid body fusing at 91°.

Phenyl-Diacetic Acid.—R. Biedermann.—After first referring to the researches of Grimaux on this subject, the author records at great length the rather circuitous mode of preparation of this substance, the formula of which is—

It is an amorphous, solid substance, fusing at 236°, but becoming decomposed at the same time.

Synthesis of Aromatic Monamines by Conversion of Atoms (Atomwandering) into Molecules.—Dr. A. W. Hofmann.—This lengthy monograph is divided into the following sections:—Investigation of the amines formed at a moderately-elevated temperature; investigation of the amines formed at a high temperature.

Conversion of Aniline into Toluidine.—Dr. A. W. Hofmann.—The preliminary account of some researches concerning which a more extensive paper will be published.

Action of Ammonia upon Nitranissic Acid and Griess's Phenyl-Diamine.—H. Sakowski.—Notwithstanding the intrinsic value of this essay, elucidated by complex formulæ, its contents are not well suited for useful abstraction.

Bulletin de l'Académie Royale des Sciences, des Lettres et de Beaux Arts de Belgique, No 6, 1872.

This number contains no original papers relating to chemistry, but we call attention to the two following memoirs:—

Lightning-Conductor Latey Destroyed by Lightning at Wetteren (West Flanders).—Drs. Glocener and Maas.—It appears that a lightning-conductor had been placed on a church recently built in this town, but it was not so contrived as practical experience has proved to be necessary to ensure a safe passage of the electric discharge, and, during a severe thunderstorm on May 23 last, the conductor was struck and broken in two places, the result being serious injury to the building. The authors examined the rods immediately after the accident, and illustrate, by means of an engraving, the damage done; they observe that, unless lightning-conductors are made with care, and tested by means of a weak galvanic current and galvanometers, they may, instead of acting as a protection, be a source of danger and serious injury to surrounding buildings.

Newly-Executed Exploration of the Bone Cavern at Engis, near Liège.—E. Du.—Illustrated with several engravings and map. This paper contains an account of the author's search for fossil bones and flint implements.

Les Mondes, August 15, 1872.

Death of M. Delaunay.—With regret we record the death of this eminent *savant*, who was drowned while bathing in the sea at Cherbourg on the 4th inst. As Director of the National Observatory at Paris, the deceased was at the head of French astronomers; he was, moreover, a scientific man of high standing, and his decease, at the early age of 56 years, will be severely felt in his native country, and be deeply regretted by all scientists who knew the value of his researches and labours.

White-Coloured Aurora Borealis.—A. Cheux.—The detailed account of the scientific observations of this phenomenon as seen at the observatory of Baumette, near Angers (France).

Observatory at Toulouse.—Rev. F. Moigno.—It appears that an astronomical-meteorological observatory, which is to be established in this ancient city, will be placed under the care of a visiting committee and director, presided over by the Mayor of Toulouse.

Electric Clockwork.—C. F. Mildé.—The exhaustive description, illustrated by several engravings, of machinery for indicating true mean time by the aid of one good clock.

Various Methods of Applying Osmose to Sugar Refining.—M. Dubrunfaut.—By osmose, the author understands a process by which the saline matter, which may impede the crystallisation of sugar, is eliminated, the operation being based upon the different degree of diffusibility of sugar and saline matter, viz., salts of potassa, soda, ammonia, and magnesia, but neither lime nor colouring matter. It appears that many beet-root sugar makers apply this method in all its technical details.

Iris Observed on the Lake of Genève.—Dr. E. Wartmann.—The account of a luminous effect of the solar rays lately observed by the author on the banks of this peculiar lake. It appears that this phenomenon is not uncommon on Lake Leman, it having been noticed in 1869.

Behaviour of Cadmium, Iron, and Tin in Nitric Acid.—Dr. Schönn.—The author states that the action of nitric acid on iron alters its nature; this is shown by its being incapable of reducing copper when immersed into a solution of that metal. Cadmium is not acted upon by nitric acid if a platinum wire is wound round the rod of metal when immersed in the acid, and the same obtains with tin. It would appear that the electric condition of the metals being altered is the cause of the effects observed.

Fulminatine.—Rev. F. Moigno.—Under this title a new explosive compound is in use, consisting of nitro-glycerine, silica, and 15 per cent of a peculiar substance, the composition of which is kept secret, but which is, on ignition, entirely converted into gaseous matter.

Pharmaceutische Zeitschrift für Russland, No. 1, 1872.

Ammonium Compound of Cantharidine.—Dr. E. Masing.—Cantharidine combines with ammonium, but this body is a rather unstable compound, and cannot be obtained in solid state except by evaporation of the solution of cantharidine in ammonia *in vacuo*. The formula of this substance is—

In 100 parts—84.85 of cantharidine, and 7.79 of ammonium. The author mentions that other compounds of these bodies exist, and also speaks of an amido combination of cantharidine which is soluble in chloroform.

No. 2, 1872.

In addition to papers more particularly belonging to pharmaceutical science, this number contains the following memoir relating to chemistry:—

Quantitative Estimation of the Alkaloids Contained in Ipecacuanha, Aconite, Nicotiana, and Conium.—Dr. O. Zenofsky.—The first instalment of an exhaustive monograph on this subject; the author reviews, in this portion, the various methods proposed for estimating the quantity of emetine present in the drug, and gives a comparative review of the results obtained by the application of the various methods. He lastly describes a plan of titration whereby, from a given quantity of ipecacuanha treated with proper solvents, the emetine may be rapidly determined; the quantity of this alkaloid present in the root varies, according to the quality of the root, from 2.425 to 3.89 per cent.

No. 3, 1872.

This number contains the concluding portion of the above essay. The author points out the best and most reliable methods for quantitatively estimating aconitine, nicotine, and conine.

La Revue Scientifique de la France et de l'Etranger,
August 17, 1872.

This number contains no original papers relating to chemistry, but we call attention to the following essay:—

Analysis of Soil by Plants.—Dr. G. Ville.—The continuation of the author's course of lectures on practical agriculture in the experimental field at Vincennes.

Polytechnisches Journal von Dr. E. M. Dingler, second number for July, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Bunsen's New Chromic Acid Galvanic Battery.—J. Müller.—This algebraico-physical essay contains the account of a series of experiments for testing the efficacy of a Bunsen battery in which,

instead of nitric acid, a mixture of bichromate of potassa and sulphuric acid is employed.

Beesmer and Cast Steel.—Dr. Dingler.—This paper treats on the relative quality of the two kinds of steel, and on the comparative value of both for technical use.

Pyrometrical Assay of the so-called Dinas Fire-Bricks and Dinas Sandstone.—Dr. C. Bischof.—This memoir records the results of a series of pyrometrical experiments made for the purpose of testing the fire-resisting quality (degree of infusibility) of these materials, which are made at Neath, South Wales. It appears that the bricks, as well as the cement and sandstone, are in a very high degree refractory, on account of containing hardly anything else than silica.

Adulteration of Ultramarine.—C. Fürstenau.—This paper contains an account of a method of mixing with genuine ultramarine white-coloured substances, such as fibrous gypsum, alabaster, and sulphate of potassa, so as to produce a deep blue, but largely weighted, ultramarine, which, however, is of course much less suitable for use.

Testing Bees'-Wax for Adulterations.—E. Donath.—The author reviews, in this paper, the labours of Landolt, Breitenlohner, Dullo, Wagner, Fehling, and others on the subject of the many adulterations of white, as well as yellow, bees'-wax. Paraffin, white resin, tallow, stearic acid, and Japanese wax are the chief adulterants. The author recommends the estimation of the sp. gr. of the substance to be investigated, and describes an apparatus, illustrated by a woodcut, for this purpose.

Contribution to the Technology of the Tanning Materials.—Dr. R. Wagner.—This monograph treats on the leather-making substances, viz., sumac, oak-bark, valonia, and bablah. The author observes that tannin (tannic acid) is not a material which is capable of producing leather with corium, and that the relative value of the tanning materials depends, not only upon the quantity of tannin they contain, but also upon accessory substances as yet only very imperfectly known.

Studies for Establishing a Scientifically-Arranged Tanning Method.—A. Reimer.—The first instalment of this lengthy monograph, divided into the following sections:—Introduction, containing a *resumé* of the labours of Dr. Knapp and others on this subject; skin; the material which causes the agglutination of the fibres; pure fibre.

Removal of Ink-Stains from Coloured Woven Tissues.—Dr. Böttger.—The author recommends the use of pyrophosphate of soda for this purpose, the salt to be applied in concentrated solution. The recent ink-stains are readily removed, but older stains require washing and rubbing with the solution for a long time.

Annalen der Physik und Chemie, von Dr. J. C. Poggendorff, No. 7, 1872.

This number contains the following original papers and memoirs relating to physico-chemical sciences:—

Passage of Caloric Rays through Diathermanic Plates when Placed in an Inclined Position.—H. Knoblauch.—An algebraico-physical monograph, illustrated by a series of tables containing results of experiments.

Experimental Researches on Fluorescence.—E. Hagenbach.—The continuation of an exhaustive memoir on this subject.

Influence of the Astronomical Motion on Optical Phenomena (viz., of the Light emitted by the Sun, Stars, &c.).—The continuation of a valuable essay on this subject.

Evolution of Heat by Friction between Fluids and Solids.—O. Maschke.—The description, chiefly in the shape of tables, of a series of results of experiments made with amorphous siliceous substances converted into small granules, and water in a peculiarly-arranged apparatus, so contrived that the amount of heat evolved by the absorption of the water by these substances could be accurately ascertained.

Magnetising Function of Soft Iron, and more particularly under the Influence of Feeble Dispersing Power.—Dr. A. Stoletoew.

Meteorite which fell June 17, 1870, at Ibbenbüren (Prussia).—G. vom Rath.—This essay, illustrated by engravings exhibiting views of the meteorite, treats at length on the phenomena observed by the falling of the stone, which mineralogically is composed of enstatite or bronzite—

Hail-Stones of Unusual Size and Shape.—A. Moritz.—The account of a severe hail-storm observed at Bjelol-Klutusch near Tiflis (Russia), at 47° 10' N. lat. and 62° 19' E. long., illustrated with engravings representing the size and shape of the hail-stones.

Microscopical Structure of Hail-Stones.—J. H. L. Flögel.—A memoir illustrated with engravings.

Apparatus for Exhibiting the Phenomenon of the Freezing of Water.—Dr. G. Krebs.—Illustrated by woodcuts.

Journal für Gasbeleuchtung und Wasserversorgung, Nos. 9, 10, and 11, 1872.

These numbers only contain papers relating to gas- and water-works' engineering.

NOTES AND QUERIES.

Test for Anthracen.—(Reply to D. G.)—Peruse Vols. 24, 25, and 26 of *CHEMICAL NEWS*, and also Dr. Kopp's memoir in *Moniteur Scientifique Quesneville*.

Lamp for Water-Oven.—(Reply to "Albion.")—Try a paraffin oil lamp with Argand burner, and get a copper chimney to it. Such a lamp gives a great heat, and can be regulated to suit any temperature.

Pure Aluminium.—(Reply to E. Purdon.)—You can only prepare this metal by decomposing solid chloride of aluminium with sodium. For the full method of manipulation consult Dr. W. A. Miller's work on Chemistry.—Z.

Dryer for Tarry Substances.—I shall feel obliged if any of your readers can inform me what dryer to use (a cheap one) to make tarry substance dry quicker. I do not mind if the lasting property of the tar is deteriorated a little.—C. E.

Manufacture of Iodine.—Can any of your readers inform me if there is any change or improvements in the manufacture of iodine other than the old method of preparing it from the mother-liquor of kelp; if so, will they kindly give a description of such improvements.—MEDICUS.

Hydrocyanate of Morphia.—(Reply to J. H. L. Schumann)—Dr. Duflos does not mention the salt you speak of, and considering the volatility and instability of hydrocyanic acid, it is not likely that a solid compound of that acid and morphia exists. There exists a cyanide of bismuth, obtainable by precipitating a solution of neutral nitrate of bismuth with cyanide of potassium, but that compound should not be used in medicine. Dissolve some pure carboic acid in water, or better still, in dilute acetic acid, and steep the meat in it for some hours. The time of immersion must depend upon the size and weight of the meat; it is then dried and cured as smoke-dried meat.—A. A.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents, 54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2276. W. B. G. Bennett, Nichols Square, Hackney Road, Middlesex, and J. C. Watt, Lancaster Road, Notting Hill, Middlesex, "Improvements in the preparation of asphalt, and in the application thereof to the construction of roads and footpaths, and other purposes."—

2286. A. Browne, Gracechurch Street, London, "Improvements and modifications in the treatment of phosphate in general, and in the production and purification of phosphoric acid and its combinations."—A communication from H. Storck, E. Hentsch, A. Hentsch, A. Lutscher, and F. Grininger, Paris.—Petitions recorded July 30, 1872.

2318. J. Henderson, New York, U.S.A., "Improvements in converting cast-iron into steel and wrought-iron, and purifying cast-iron for foundry and other purposes."—Petition recorded August 3, 1872.

2331. C. M. T. du Motay, Boulevard de Strasbourg, Paris, "An improved mechanical and chemical method of epurating the cast-irons, in order to allow the same to be directly or indirectly transformed into iron or steel."—Petition recorded August 5, 1872.

2341. C. Morfit, Baltimore, Maryland, U.S.A., "Improvements in the manufacture of pure phosphates of lime."—Petition recorded August 6, 1872.

2351. G. M. Moore, Liverpool, "Improvements in the process of evaporating or concentrating alkaline liquors in the manufacture of caustic soda, caustic potash, soda ash, and other similar substances; also for heating or boiling and refrigerating solutions in breweries, distilleries, chemical and other manufactories, and in the apparatus employed therefor."—Petition recorded August 7, 1872.

INVENTIONS PROTECTED BY THE DEPOSIT OF COMPLETE SPECIFICATIONS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of Six dollars or £1 2s. 4d. per annum payable in advance.

THE CHEMICAL NEWS.

VOL. XXVI. No. 665.

ON THE FUSION OF METALLIC ARSENIC.*

By J. W. MALLETT, Ph.D., M.D.,
Professor of Pure and Applied Chemistry, University of Virginia.

EXPERIMENTS on this subject, made by Mr. Dunnington and Mr. Adger, students in the Laboratory of the University of Virginia, under the author's directions, were described. These experiments had been undertaken in view of the generally repeated statement that arsenic cannot be fused, but passes directly from the solid into the vaporous state, and that an attempt to secure increased pressure by using a sealed tube only results in bursting the tube. The statement by Landolt† (given apparently without further details) that, by using a glass tube enclosed in one of iron, the metal heated for some time to low redness under pressure may be melted into globules, was noticed only after the experiments to be mentioned had been made.

Arsenic, in the form of small fragments and coarse powder, was placed in a thick barometer-tube of soft glass and of small bore, well sealed at both ends and enclosed in a piece of wrought-iron gas-tubing closed at each end by an iron screw cap; the space between the two tubes was filled with sand well shaken down, and the whole was heated to redness by a charcoal fire. Another similar iron tube placed beside the former served to contain several little glass tubes with samples of different metals whose fusion might afford some indication of the temperature at which that of the arsenic occurred.

Arsenic thus treated was found, on cooling, to have fused into a perfectly compact crystalline mass, moulded to the shape of the tube, of steel-grey colour and brilliant lustre, of sp. gr. = 5.709 at 19° C. It possessed a considerable degree of cohesive strength as compared with common sublimed arsenic, and even seemed to exhibit faint traces of flattening before crushing under the hammer. It gradually tarnished on exposure to the air, and presented all the chemical properties of ordinary crystalline arsenic obtained by sublimation. The temperature required for fusion lies between the melting-points of antimony and silver.

The glass tube used was found greatly distended by the tension of the vapour, and the siliceous sand, even when of the purest kind (from Fontainebleau), and previously well washed with hydrochloric acid, and then with water, was cemented together (in a way very interesting in connection with the history of metamorphism) into a kind of artificial sandstone. Specimens of fused and semi-fused arsenic, and of the tubes surrounded by a thick crust of compacted sand, were exhibited to the Section.

ON A MODIFICATION OF HOFMANN'S APPARATUS FOR ELECTROLYSIS OF WATER.*

By C. J. WOODWARD, B.Sc.

THE extremely convenient arrangement of Dr. Hofmann for showing the composition of water by electrolysis is, owing to its first cost and delicate construction, only accessible to those who are able to make a considerable expenditure in apparatus. The modification I have used

in my class lectures is in every way as serviceable, and has the advantage of being fitted up at a small cost. The arrangement is as follows:—A glass cylindrical vessel, about 5 centimetres diameter and about 6 centimetres high, has ground into it a stopper in which are three holes, each hole being about 15 m.m. diameter. In two of these holes are fitted the tubes intended for the reception of the gases, oxygen and hydrogen, whilst the remaining hole serves to insert a third tube to contain the acid expelled as the gases are formed. The tubes for collecting the gases have electrodes made by cutting strips of platinum foil, which are cemented lengthwise on the tube and hang a centimetre or so down below the edges of the tubes. Pieces of caoutchouc tube are used to make the tubes acid-tight, and to make the apparatus firm a triangular cork wedge is placed within the tubes. Instead of glass cocks, as in the arrangement of Hofmann, pinch-cocks are used, as I found these much more manageable, besides being cheaper. The apparatus, when charged with dilute acid of 1 to 4, will give off about 15 c.c. of gases per minute when four pint cells of Grove's battery are used.

ON THE DUST THROWN UP BY VESUVIUS IN THE RECENT ERUPTION.*

By GEORGE GLADSTONE, F.C.S.

DURING the eruption of Vesuvius which took place last spring, Naples and the surrounding country was visited by a shower of fine black dust. In some places the fall was very heavy, and even in Ischia, at twenty-five miles distance from the mountain, where the dust examined was collected, the quantity was sufficient to cause great annoyance to the inhabitants. It consisted of aggregations of crystallised quartz, dotted over with the magnetic oxide of iron. This ferroso-ferric oxide was also crystalline, and possessed a high metallic lustre. The grains were very uniform in size, and would pass through a wire gauge the apertures of which measured the 16,000th part of a square inch. By boiling the sand in hydrochloric acid, the whole of the iron is removed, and nothing but crystals of pure white quartz remained. Its composition is the same as that of the iron sand which is found in the soil in some parts of the country round Vesuvius, and which is the product of former eruptions; the latter, however, contains a larger relative proportion of iron, and the grains show a water-worn appearance under the microscope. Neither of the Vesuvian specimens contain titanium, which is found in the magnetic iron sand of New Zealand, which has most likely been ejected from the great volcano of Mount Egmont.

PRELIMINARY NOTE ON "GUARANINE."*

By JOHN WILLIAMS, F.C.S.

THE fruit of the *Paulina Sorbilis* is made up into rolls by the Indians of Para, in South America, and is by them called "Guarana." Its infusion is used as a beverage, and within a few months has been introduced into medical practice, and recommended as a remedy for sick headache.

Dr. Stenhouse some years back examined guarana, and isolated the crystallisable principle, which he named guaranine, but considered it to be identical with caffeine or theine.

I considered it a matter of interest to prepare some of this substance, and first proceeded to do so by the process given by Stenhouse, but found it troublesome, and the

* Read before the British Association, Brighton Meeting, Section B.

result not so satisfactory as might be desired. This led me to adopt the following process, which I found in every way satisfactory.

Guarana reduced to a fine powder, is mixed with one-third of its weight of hydrate of lime, and moistened with water. After an hour or two it is placed in a drying closet, and completely dried at a moderate heat. This is exhausted with boiling benzole, filtered, and the benzole distilled off, when a small quantity of light-coloured oily matter is left. This is treated with boiling water, and the whole digested over the water-bath until all traces of benzole have been dissipated, then filtered through a wetted filter so as to keep back the oil; the aqueous portion evaporated to a small bulk, and set on one side for 24 hours, yields the guaranine white and pure, in fact requiring no further purification of any kind. I have tried the process upon tea, and it appears to answer, but have not yet finished my experiments in that direction. As far as appearance goes, guaranine appears to be identical with theine and caffeine, but the author suspects it will be found to be rather more soluble in water, and not quite so bitter in taste as the above mentioned bodies.

ON THE OXIDATING POWER OF IODATE OF POTASSIUM.

By E. SONSTADT.

I. In the Dry Way.

ABOUT a year ago I found a mineral, subsequently traced to the lime brought from Castletown, which closely resembled anthracite in appearance, but could not be scratched with a knife. Its hardness, in the best specimens, was about 6.5. The specific gravity of a piece that had evidently been heated with the lime among which it was found was 1.689. A specimen picked up in a street in Castletown, which did not appear to have been in the fire, had sp. gr. 1.3852. A splinter of the mineral heated before the blowpipe appeared to be unaffected, while splinters of anthracite and of gas-retort carbon similarly heated were burnt without difficulty. The finely-powdered and levigated mineral was scarcely attacked by nitre at a red heat—while fragments of anthracite and of gas-retort carbon were deflagrated in the same crucible, the powder remaining intact even after the intense heat thus produced. The powder was fused with caustic soda; and with chlorate of potassium with like apparently negative result; although always in these experiments the mineral lost in weight. A portion heated with carbonate of sodium for several hours in a forge-fire was found to have lost about half its weight, but I could detect only traces of substances in the alkaline solution. Digested for several days with strong acids, only traces of matter were dissolved. Heating with acid chromate of potassium and sulphuric acid was likewise resultless; but when the powder, or even fragments of the mineral, were mixed with iodate of potassium, and heated in a glass tube, deflagration ensued, and a gas (unaccompanied by iodine when the purest specimens were used) was given off, which gave, when conducted into an ammoniacal solution of chloride of barium, a white precipitate, which dissolved in acids with evolution of an inodorous gas, capable of extinguishing flame. The substance is, therefore, carbon. The mineral is not absolutely unattacked by the processes that have been described. Its behaviour before the blowpipe is precisely that of the diamond, which in small fragments may, as well as this mineral, be thus burnt, though very slowly. But I think that this mineral is quite as difficult of oxidation as the diamond, which latter, however, I have (many years ago) only examined in very small fragments before the blowpipe. From the similarity of the behaviour of the two minerals when heated in the blowpipe-flame, it may be supposed that diamond-powder would, like the black mineral, deflagrate when heated with iodate of potassium.

Many specimens of this mineral show ligneous structure quite plainly—some even look like wood turned black. There is a great difference in the purity of the specimens, most of which are more or less clogged in pores with lime introduced in the kiln. The aqua regia with which, in one experiment, several grammes of the finely-powdered mineral were heated for two or three days was found to have taken up traces of silica, alumina, lime, magnesia, lithium, sodium, and potassium. The merest traces, however, of the first four of these substances could be detected in the residue left on deflagrating purer specimens of the mineral with iodate of potassium. I have not had an opportunity of finding out whether this mineral belongs to the limestone of Castletown, or to the coal with which the limestone is burnt. By workers with the lime, the mineral was explained to me to be coal that had escaped burning. If this mineral, as little combustible as the diamond, nearly as hard as quartz, and having a higher specific gravity than anthracite, should be regarded by mineralogists as a distinct variety of carbon, then *tetratomic* carbon will have been recognised in *four* varieties or allotropic conditions. I believe that no monatomic substance is known to have any allotropic modification, whereas several polyatomic elements, as sulphur, phosphorus, selenium, boron, and antimony, are known to have such modifications.

A few experiments upon the action of melted iodate of potassium upon some minerals, particularly sulphides, have been made; but the results are as yet too incomplete to be worth communicating. Probably the reason of the great power of iodate of potassium as an oxidizing agent in the dry way, as compared with chlorates and nitrates, is because it acquires a sensibly higher temperature than chlorate of potassium before it decomposes, and when it does get hot enough to decompose, the oxygen it gives off is pure and in abundance; whereas nitrates under like heating, or at a much higher temperature, give off mixed gases.

II. In the Wet Way.

After discovering the presence of iodate of calcium in sea-water, and getting a clue, by some preliminary experiments, to the important function it performs there, it seemed desirable to trace carefully, by experiments, the limits of the oxidating power of iodic acid in a neutral or alkaline liquid—first, upon oxidisable inorganic compounds; and, secondly, upon some definite (so-called) organic substances and upon putrescible matter. Thus far, all my experiments greatly strengthen the views expressed in my papers on "The Presence of Iodate of Calcium in Sea-Water," and confirm the statement that a minute proportion of an iodate in a neutral or alkaline liquid containing much putrescible matter has, practically, unlimited power in preventing putrescence, and in arresting its progress when begun, by transformations which render innocuous as air-poisoners the foulest smelling substances. As has already been explained, the peculiarity of the agent lies in its power of continually reproducing itself after it has undergone reduction. Long known reactions suffice, in a general way, to account for these phenomena. That some iodides, and notably those of calcium and of barium, are decomposed when their solutions are exposed to the air, with formation of carbonates and separation of iodine, is a familiar fact. That such solutions, if containing also strong bases in excess, should under like circumstances have an iodate formed in them instead of free iodine, is only a widening of statements that have remained unchallenged for years; such as, that iodide of potassium containing free alkali or alkaline carbonate absorbs carbonic acid from the air; and that the formation of a carbonate is accompanied in this instance by the formation of an iodate. These reactions go on slowly; but their progress may be made sensible in a few hours by, for example, passing carbonic acid gas to saturation through a solution of an alkaline iodide, to which some chloride of barium or of calcium, and a little alkaline carbonate, have

been added. Traces of an iodate are formed; and on exposing the liquid in an open dish to the air, the proportion of iodate increases, so that in a day or two it may be quite easily recognised. My experiments teach that carbonic acid is not capable of effecting this change without the presence of atmospheric oxygen; for I find that, in a close vessel charged with carbonic acid, the trace of iodate at first formed (which does not afterwards increase in quantity by further passage of carbonic acid gas) is not apparently greater than the oxygen originally contained in the air dissolved in the liquid might be supposed able to account for. But such a liquid, exposed to air, goes on forming an iodate continuously. I have more to communicate on this subject that would be out of place here, and which I keep for another time. At present, I desire only to point out that the formation of an iodate under atmospheric conditions has been noticed before me, and that an experimental confirmation of the natural formation of an iodate in such manner is very easy to be obtained. I have always found the washings of the ash of sea-weed to contain an iodate after long exposure; and this formation of iodate, if neglected, might lead to considerable loss, since sparingly soluble iodate of calcium remains with the residue after lixiviation. Ordinarily, however, kelp contains sulphides, and until these are oxidated to thiosulphates no iodate is produced. And now we come to the consideration of the reactions in the wet way between

Iodates and Thiosulphates.

There is, I believe, an impression prevalent that the alkaline thiosulphates undergo oxidation by exposure to air in solution, or by long keeping, with access of air, in a moist state. I have found, however, that long keeping increases the purity of thiosulphates, owing to the oxidation of sulphides, or, possibly, of other oxides of sulphur than thiosulphuric acid. Some thiosulphate of sodium that I had by me for ten years in a loosely-stoppered bottle, often exposed to moist air, contained after that time no sulphate. It had become very pure, as has been described. A recognition of the great stability of the thiosulphates is of importance in connection with what follows.

Solutions of pure iodates and thiosulphates, mixed in any proportion in strong or in dilute solutions, with or without access of air, in sunlight or in shade, undergo no change. Some of the experiments extended over about three months, but in no case could I detect the slightest indication of any chemical action having taken place. The mixed solutions remain neutral, and the iodic acid may be fractionally separated from the thiosulphuric acid by precipitation of the highly diluted liquid by a soluble barium salt. No sulphate is formed; but the addition of an acid in small proportion to the mixed solution turns it strongly alkaline. Further addition of acid precipitates iodine after the neutral point is passed, if the iodate is present in excess, and in such case, if hydrochloric acid is used, sulphuric acid is formed. If the proportion of iodate to thiosulphate is that of one atom, or less, of the former to six of the latter, the liquid remains perfectly colourless and limpid on addition of excess of acid, and the only products are water, a tetrathionate, an iodide, and a salt of the acid used. Carbonic acid gives no reaction. With hydrochloric acid, the formula, determined by several closely-agreeing experiments, is—

Iodates and thiosulphates may, therefore, both exist together in solution, and yet in the ordinary course of analysis both escape observation. The fact that they do actually exist together in solution very commonly has just been referred to.

When citric acid is used, instead of hydrochloric acid, to acidify the mixed solutions of iodate and thiosulphate, the solution becomes neutral to test-paper, sensibly before iodine is set free, in the solution containing a trace of

iodate in excess. The equation representing the reaction up to the point of neutrality to litmus-paper is—

This reaction seems to indicate that trimetallic sodium citrate is not really neutral, as usually stated, but has an alkaline character; since, to get an iodine reaction (a trace of iodate in excess being used), a quarter atom of citric acid, in addition to the two atoms already used, had to be added, which gives, after multiplying the equation into four for avoidance of fractional coefficients—

This reaction implies exact chemical neutrality; and here we have exactly one-third of the hydrogen atom belonging to the citric acid displaced by sodium atoms; or, the number of atoms of the latter to those of the former is as 1 : 2.

With tartaric acid, the liquid becomes neutral to litmus-paper when the proportions used are—

a formula entirely correspondent to that already found (2) under identical conditions for citric acid, notwithstanding that citric acid is considered a triatomic, and tartaric a tetratomic acid. The addition of one more atom of tartaric acid to the liquid exactly gives the iodine reaction, a trace of iodate in excess being present as before.

an equation also corresponding in significance to that found for citric acid (3), the number of sodium atoms being to the number of hydrogen atoms as 1 : 2; only here this proportion does not show as remarkable, because the tartrate formed has the composition of an ordinary neutral tartrate, which salt is, therefore (unlike so-called "neutral" citrates), really chemically neutral.

This mode of investigating the constitution of acids and their salts is evidently capable of being extended to a very large class, and suggests a ready, as well as most accurate, volumetric method of estimating many acids—tartaric and phosphoric acids, for instance. As a preliminary experiment in this direction, I put, to a weighed portion of pure acid tartrate of potassium, about its own bulk of sulphate of calcium and chloride of potassium moistened with dilute sulphuric acid, added water, supersaturated with carbonate of sodium, and evaporated, with addition of hydrochloric acid in excess, to dryness on the water-bath until acid odour ceased to be given off. The residue was treated with a properly adjusted solution of iodate of potassium and thiosulphate of sodium until a slight permanent colour reaction was obtained, and then just caused to disappear. The quantity of reagent that had been used was ascertained by weighing the flask containing it before and after testing, and this quantity was found to agree, within the limits of gravimetric errors, with the quantity of the reagent which corresponded exactly with all the tartaric acid contained in the weighed quantity taken of acid tartrate. Hence, although tartaric acid precipitates an acid tartrate from neutral solution of sulphate or chloride of potassium, yet when a tartrate is evaporated to dryness with hydrochloric acid in excess, under the conditions described, the whole of the tartaric acid is set free and admits of easy and accurate estimation.

From what precedes, it may easily be perceived that, in the mixed solutions of an iodate and a thiosulphate, we have an instrument of great delicacy and facility of application for the determination of the relations existing between the atomic weights of several elements. With a trace of iodate in excess, it matters not whether the acid added to give the reaction be added in large or in ponderably inappreciable excess. In either case, the reaction is quite sharp and definitely fixed. If, for instance, such a liquid were formed

with accurately weighed portions of iodate of potassium and thiosulphate of sodium, adjusted to give with sulphuric acid a faint iodine reaction, then the substitution of an exactly equivalent proportion of iodate of sodium, say, for the potassium salt, would be indicated by the same reaction; and an imponderable excess or deficiency of the sodium salt might be estimated by a volumetric determination of the iodine set free—a sufficient excess of iodate in such case being used in both experiments to allow a margin for errors in weighing. It is not even necessary that the thiosulphate should be pure. Commercial "hyposulphite of soda" in solution becomes opalescent from precipitated sulphur when an iodate is dissolved in it; but, with a very slight excess of iodate, the liquid clears itself after a day or two, and becomes fit for use. For ascertaining the atomic weights of acids, referred to a pure iodate as a standard, the method is equally applicable.

Evidently, all acids capable of acting at all should produce precisely the same effect (provided they are not capable of acting chemically upon pure solutions of iodides or iodates) upon portions of the same solution of iodate and thiosulphate, *if the atomic weights of the elements are invariable in whatever juxtaposition they may be placed.* But if the elements can, whether according to their densities, degrees of affinity, or other conditions, include in close embrace proportions of one another more or less modified by such conditions, then this method ought to show such to be the case, even although such modifications were within a range far too narrow for certain detection by gravimetric processes. Of course the atomic weight of the acid used to produce the reaction does not influence the result, since, whatever acid is taken is supposed, in the kind of experiment now being considered, to be used in excess. But if, for instance, the weight of potassium in an atom of sulphate of potassium is not absolutely identical with the weight of potassium in an atom of, say, acetate of potassium, such a difference must necessarily be made evident by the necessity for a different adjustment of the proportions of iodate to thiosulphate in the test-liquor, in the cases, respectively, of acidulating by sulphuric or by acetic acid. And, in fact, *just such differences do exist.* A liquid that shall give a distinct colouration with sulphuric acid shall remain absolutely colourless with excess of some other acids (acetic acid of the number); and these also diverge, although by exceedingly small differences; so that I do not think the entire swing between the extremes of these differences that I have observed is sufficient in amount to have admitted of its certain discovery by preceding methods of investigation. Such differences, if found at all, would be referred by general opinion, if not by the experimenter himself, to impurities in the substances experimented upon, or to errors of weighing, or other sources of error which appear to be in part minimised, and in part excluded in the instance before us, by the very nature of the process. Indeed, a nicely adjusted solution of iodate and thiosulphate is itself a balance of nature's own providing; the colour reaction being the passage of the index just past zero, or the point at which the iodate is exactly reduced to iodide. And since, whatever proportion of iodate is in excess, must, on acidulating, occasion the precipitation of six proportionals of iodine, such passage of the index past zero is indicated with great nicety.

In conclusion, some reference should be made to the well-known reaction for the production of tetrathionates ($2\text{Na}_2\text{S}_2\text{O}_3 + 2\text{I} = \text{Na}_2\text{S}_4\text{O}_6 + 2\text{NaI}$), which lies at the root of the reaction I have been describing. In the text-books, it is usually directed, in the preparation of tetrathionates, to filter off the precipitated sulphur. But, according to the equations given, no sulphur ought to separate. To examine this, I prepared some chemically pure iodine according to the process devised by Stas, and given by him in his papers on the atomic weights of some elements. This iodine, added to solution of thiosulphate of sodium,

dissolved to a perfectly limpid solution, nor, when added in excess, did it separate any sulphur. I name this chiefly because it suggests a convenient test for the impurity of iodine. Iodine which precipitates sulphur from solution of pure thiosulphate of sodium is certainly impure; but I am not prepared, on the other hand, to say that iodine which does not precipitate sulphur from such a solution is necessarily free from all kinds of impurity, although such non-precipitation of sulphur would certainly look well.

PROCESSES FOR DISTINGUISHING AND SEPARATING SILK, WOOL, AND VEGETABLE FIBRES IN MIXED TISSUES.

By EMILE KOPP.

THE processes generally employed depend either upon the manner in which animal and vegetable fibres behave with certain reagents, or upon their greater or less affinity for different colouring materials, especially artificial colouring matters. In order better to appreciate the value of the processes indicated, it will be well to recall the principal reactions presented by textile fibres.

Vegetable fibres, (cotton, linen, hemp, &c.) all having cellulose for a base, resist very energetically the action even of boiling aqueous solutions of the caustic alkalies, but they are strongly attacked by concentrated acids, (sulphuric, nitric, and hydrochloric) and even by these acids considerably diluted with water, when acted upon by heat. Thus it is possible to immerse a cotton tissue without great injury, in cold water containing in 100 parts 5 to 10 parts of acid; but if the solution is heated, especially if it is boiled, the cotton soon becomes friable, then dissolves, and is transformed successively into gum and sugar. It is to be observed, however, that fuming nitric acid, or a mixture of nitric and sulphuric acids, does not dissolve vegetable fibre, but transforms it, almost without changing its physical aspect, into gun-cotton or pyroxylin. Ammonia is absolutely without action on cotton or hemp, either in the heat or cold; but if a solution is made of hydrated oxide of copper in ammonia (Schweitzer's blue liquor) which is a solution of the oxide of cupr. ammonium $[(\text{NH}_3)_4\text{Cu}]$ cotton, hemp, and finally linen, are dissolved by it. Vegetable fibres, when pure, have ordinarily little affinity for artificial colouring matters, and are only coloured very faintly or not at all by such dyes. A slight application of soap is sufficient to remove the colouration. Cellulose also resists tolerably the action of chlorine, and hypochlorites, and has no characteristic odour when burned.

Wool, unlike cotton, resists pretty well the action of acid solutions, even when rather strong and warm; but caustic lyes destroy its state of aggregation and dissolve it, particularly when hot. As wool contains sulphur, its solution in caustic soda gives rise to sulphide of sodium which blackens acetate of lead. Nitric acid colours wool an intense yellow; chlorine and the hypochlorites also alter it, giving it a like yellow. Schweitzer's reagent is without action in the cold, but in presence of heat the wool is dissolved. In the decomposition of wool by heat it gives off the characteristic odour of burnt horn. Wool presents a remarkable affinity for colouring materials in general, and especially for artificial colours, which dye it with the greatest facility even without the aid of mordants. Silk gives in burning a similar odour to that of wool. It is dissolved by the strong concentrated acids, particularly when hot. Cold nitric acid colours it yellow. Acids diluted with water have not a very vigorous action. Concentrated alkalies dissolve silk as they do wool, but the solution does not contain sulphide of sodium. The alkalies, much diluted with water alter, but do not dissolve it; ammonia has no action on it, but Schweitzer's solution liquefies it, as it does cotton. Silk resembles wool in its affinities for colouring matters.

Let us now examine successively the processes which may be used, first, to recognise the different kinds of textile fibres in mixed tissues, and second, to separate them so that one or the other of these may be used again; omitting all unessential details. We will here speak only of purely chemical reactions, remembering, however, that the microscope is of valuable aid in identifying textile fibres. These, according to their origin, present textures wholly distinct, which by themselves are sufficient to characterise the different species.

To recognise the presence of Vegetable Fibre (Cotton, Hemp, Linen, Jute, &c.) in a tissue of Wool and Silk, it is only necessary to boil the fabric in an aqueous solution of caustic soda (100 parts of water to 10 parts of fused caustic soda). The wool and silk are dissolved, but the vegetable fibre is not attacked, and remains as a residue retaining its essential characteristics. To better distinguish it in case it has been coloured, the whole is thrown on a little calico filter, and washed with hot water. The washed fibre is then laid out in tepid water acidulated with about 5 parts in 100 of hydrochloric acid. After 10 minutes, a little chlorine water or a few drops of solution of chloride of lime is added, either of which bleaches vegetable fibres. The filtrate of the caustic soda solution which holds the wool or silk, may be tested immediately for wool. If this latter is present, sulphide of sodium is formed, which remains in the solution; its presence may be detected by adding 2 or 3 drops of acetate of lead. If a white precipitate is formed, which redissolves completely upon agitation, the tissue must have been of silk simply; but if, on the contrary, there appears a permanent black precipitate of sulphide of lead, it contained wool. For acetate of lead, a few drops of solution of nitroprusside of sodium may be substituted, which gives a beautiful violet colour, in presence of sulphide of sodium.

When the fabric is strongly charged with colouring matter, it may be advantageous to operate in the following manner. A mixture is prepared of 2 volumes of sulphuric acid, concentrated to 66°, and of 1 volume of equally strong and fuming nitric acid. After the mixture has cooled, the tissue, cut into small pieces, is immersed, and allowed to remain for 15 or 20 minutes, with agitation from time to time. The wool, silk, and colouring materials are oxidised and destroyed, but the vegetable fibre is transformed into gun-cotton or insoluble pyroxylin retaining its characteristic fibre. The whole is thrown into a large quantity of water, where the gun-cotton is deposited. The fluid is decanted and the residue collected upon a filter, thoroughly washed and dried. The dried residue then presents fulminating properties very characteristic of gun-cotton. For mixed fabrics which are white or not too deeply coloured, recourse is had to the affinity of animal fibres for artificial colouring agents. A tissue dyed in deep colours should be previously decolourised by immersion in weak chlorine water, and a subsequent thorough washing with boiling water. There are, however some precautions to be observed, since cotton is also capable of being dyed in baths of aniline colours, especially if it is impregnated with feculent substances, and others which enter into the composition of the preparations.* The preparation must therefore be removed. This is effected by boiling the tissue 10 minutes in water containing in 100 parts 2 parts of carbonate of soda and a little soap, rinsing in hot water, and then immersing for 5 or 10 minutes in water at 50° to 60°, holding 2 parts in 100 of hydrochloric or sulphuric acid, and finally washing thoroughly. The colouring-bath is in the mean time prepared in the following manner:—(we will choose for example, red aniline or fuchsine.) A few decigrammes of fuchsine are dissolved in 25 or 30 c.c. of water, the solution boiled, and during ebullition, caustic soda is added drop by drop, until it presents only a light rose tint. It is then removed from the fire, and the tissue put into the liquor. After a few minutes it is taken out, well washed with pure

water and dried. The threads of silk and wool are then found to be dyed a beautiful vivid red, while the vegetable threads, cotton, flax, &c., remain entirely uncoloured.

To recognise the presence of Wool in Silk, and vice versa.—If the tissues are white or slightly coloured, the presence of sulphur in the wool may be made use of. A solution of oxide of lead in caustic soda is first prepared by boiling litharge in the latter, allowing it to settle and decanting the clear liquor. In this is placed the tissue. The threads of wool which contain sulphur, naturally become immediately black, owing to the formation of black sulphide of lead; while the silk threads which are without sulphur, do not change their shade. Professor Stefaneli, of Florence, has advised the use of Schweitzer's liquor; that is to say, the solution of hydrated oxide of copper in ammonia. He works as follows. A piece 2 centimetres square of the tissue to be examined is put into 10 or 12 c.c. of the blue copper liquor. At the end of 5 or 6 minutes the silk is dissolved, while the wool is not in the least attacked. If the silk should be dyed black, it is necessary to take a double volume of the liquor and prolong the contact to 10 or 12 minutes. After removing the wool the blue liquor quickly supersaturated with nitric acid does not give a sensible precipitate. But if a vegetable fibre should be present, which is generally dissolved, although much more slowly by Schweitzer's liquor, this, upon saturation with nitric acid, will give a precipitate of cellulose, under the form of white or light-coloured flocks. A more simple process consists in employing concentrated acids. Ordinary nitric acid dissolves silk in the cold, without sensibly attacking wool. It is the same with cold sulphuric acid when sufficiently concentrated. This acid at the same time clears the wool of vegetable fibres, which become transformed under these circumstances into gummy matters or sugars. But it appears preferable to employ concentrated hydrochloric acid, used cold, immersing the tissue in the acid. In a short time the silk is completely dissolved, the wool and vegetable fibres remaining unaltered. Water is added and fibres not attacked (consisting of wool and those of vegetable origin) are collected upon a filter where they are perfectly washed. Generally they are then to be decolourised. To identify them recourse may be had either to the action of boiling caustic soda-lye, which dissolves only the wool, or to artificial colouring matters, fuchsine, aniline violet, or nitropicric acid, which do not colour cotton,* if one works with proper precautions. In all these trials it is always well previously to clear the tissues to be examined of their preparations† and colouring matters; the former by successive treatment with boiling water, either pure or slightly acidulated, or rendered alkaline by a little carbonate of soda; and the latter by chlorine water, &c., finishing always with a thorough rinsing in pure warm water, after which the tissue is dried.

Industrial Separation of Animal and Vegetable Fibres.—The utilisation of rags has given birth long since to important industries. Cotton, linen, and hemp rags, old ropes, &c., are the foundation for the manufacture of paper. Pure woollen rags serve for the preparation of worked-over wool (shoddy) which spun with new, enters into the manufacture of a number of woollen tissues. We will here especially consider rags of mixed wool and cotton, which it is convenient to class in two divisions.

1. Rags in which vegetable fibre mostly predominates, and which are suitable for the manufacture of paper.

2. Rags containing so much wool that it is advantageous to destroy the vegetable fibre, in order to separate the former and render it fit for use.

I. In well-organised paper-mills the wool, in rags containing but a small quantity of it, is separated as exactly as possible by mechanical means, and the remainder of the tissue reserved. If a little wool still stays with the

* French, "qui ne teignent pas la laine;" le coton is evidently meant, as it is asserted on a preceding page, "La laine présente une très-grand affinité pour les matières colorantes en général, et surtout pour les couleurs artificielles."

† Apprets.

* French "apprêts," English equivalent, "stiffening," or sizing.

rag of vegetable fibre, it ordinarily disappears completely in the operation of cleansing and bleaching, especially during the boiling in closed vessels with quick-lime or caustic soda, to which hemp, linen, or cotton rags are submitted before passing to the chlorine or being treated by the unravelling machines. It frequently happens that after picking the mixed rags, there remains refuse containing a sufficient quantity of wool, but of such bad quality that it cannot be utilised as a textile fibre. If it is desired to treat these rags with caustic soda-lye with a view to dissolving the wool and isolating the vegetable fibre, the final product applicable to paper-making, it is not worth while to go to this expense to accomplish it. In such cases the process employed is that of Mr. Ward. It consists in submitting these rags to the action of vapour of water under a pressure of from 3 to 5 atmospheres. At this temperature under the influence of superheated steam, the wool is converted into a blackish substance, friable, and easily separated mechanically in the state of a dry powder, leaving the vegetable fibre intact, and suitable for the preparation of paper-pulp. The powder of altered wool contains still all its original elements, and constitutes an excellent manure; indeed, it contains 73 parts in 100 of organic matter, and 10 to 12 parts in 100 of nitrogen, corresponding to 12 to 14 in 100 of ammonia.

II. Mixed rags, rich in wool, still of tolerable quality, are submitted to processes designed to destroy the vegetable fibre. The method most generally followed consists in well impregnating with water, containing 5 to 10 parts in 100 of sulphuric or hydrochloric acid. They are left to drip, pressed slightly, and then laid out upon the floor of a desiccator, the temperature of which is raised gradually towards 100°. They remain here during several hours according as they are thicker or thinner. Owing to the evaporation of the water, the acid is concentrated in the rags, and with the aid of heat it reacts upon the vegetable fibre, transforming the cellulose into gummy matters and sugars. After this, the vegetable fibre becomes very friable, and may then be separated mechanically from the wool, which has preserved its textile qualities. But this process needs to be managed with much precaution, and to be well watched, because under the influence of acids and an elevated temperature the wool may be altered, losing its sweetness, and also the property of felting with facility. Some makers, for this reason, work as described below. Instead of exposing the dry rags to an elevated temperature, they dry them at a gentle heat, 40 to 50°, then submit them to steaming (that is to a current of dry steam*) and afterwards dry them once more. The vegetable fibre is thus rendered friable and pulverulent. With mixed rags of very good quality, solutions of oxalic acid are sometimes substituted, or hydrochlorate of albumen for sulphuric or hydrochloric acid; these substances destroy the vegetable fibres without sensibly attacking the wool.

Instead of the drying operation, the mixed rags may be treated in the moist way. This is Seloup's process. In this process a bath of hydrochloric acid diluted with three or times its volume of water is prepared in a wooden vat. By means of a jet of steam the bath is warmed to about 90°, and at the same time the rags are immersed in it. The jet of steam is arrested when the bath appears upon the point of boiling. At the end of from 30 to 50 minutes, the vegetable fibre is dissolved. The rags are then removed, allowed to drain into the bath (which may be used several times,) and finally wrung out. They are next washed with water until free from acid; but it is preferable to throw them, still slightly acid, into a solution of carbonate of soda, and to stir vigorously. The soda saturates the acid, and at the same time liberates carbonic acid, which, escaping through the woollen fibres rises and swells them, separating them one from the other. The quantity of carbonate of soda should be just sufficient to neutralise the acid. The wool is

* "Au vaporisage, c'est-à-dire à un courant de vapeur plutôt sec que humide."

afterwards washed thoroughly with running water. In order to render it sweet, it is then passed through a tepid soap-bath, which is followed by another washing, when it is at last dried at a gentle heat.

The English process of Mr. Stuart, rests upon the fact that wool impregnated with a salt of alumina, is not subject to loss of its qualities under the influence of hydrochloric acid and an elevated temperature. 50 kilogrms. of sulphate of alumina of commerce ($\text{Al}_2\text{O}_3 \cdot 3\text{SO}_3 + 18\text{aq.}$) and 25 kilogrms. of common salt, are dissolved in 450 litres of water. The rags are impregnated with this solution, allowed to drain, squeezed out slightly, and dried. They are then exposed during several hours to a temperature of 90° C., when the sulphate of alumina forms, by double decomposition with common salt, sulphate of soda, and chloride of aluminum. This last is decomposed in turn, alumina and hydrochloric acid being formed under the influence of heat (a certain quantity of bisulphate of soda is formed at the same time) the latter substance attacking the vegetable fibres. These become very friable, and may afterwards be separated mechanically in the form of dust. For strong and thick rags, a much more concentrated solution is employed, containing in 450 litres of water, 75 kilogrms. of sulphate of alumina, and 40 kilogrms. common salt. Instead of squeezing out and afterwards heating to dryness the impregnated rags, they may be boiled in the solution, or steamed by a jet of moist steam so that the vegetable fibres will become friable or even soluble in water. Another Englishman, Mr. Rowley, treats the mixed rags with weak sulphuric acid, permits them to drain, presses out the excess of acid liquor, and dries them by a current of warm air in a sieve of wire-gauze* kept constantly in motion by machinery. They are then put into heated sand, where they are manipulated until, by friction against the grains, all the cotton has been pulverised and detached. The separation of the sand from the fibre of wool, which in this process is more or less protracted, is finally accomplished very easily by mechanical means. This process gives good results and is inexpensive. We think that the most rational and economical means consists in employing a bath of sulphuric or hydrochloric acid, containing 300 to 500 parts of water to 100 of acid. The rags are left to drain, aired or pressed out a little, and dried slowly, the temperature of the stove or of the current of dry air being gradually raised to 70°, or in certain cases even to 90°. This temperature should be maintained through several hours, and the more as the vegetable fibre is tougher or harder to destroy. If it is wished to really guarantee the wool, it will be well to use a mordant of alumina, which is made quite simply by adding to 100 parts of an acid bath, 1 to 2 parts of sulphate of alumina of commerce ($\text{Al}_2\text{O}_3 \cdot 3\text{SO}_3 + 18\text{aq.}$), or even of ordinary alum.—*Moniteur Scientifique.*

ON THE EVIL EFFECTS OF THE USE OF ARSENIC IN CERTAIN GREEN COLOURS.†

By FRANK W. DRAPER, M.D.

(Concluded from p. 92).

Who are the victims of the unnecessary, yet too common, practice of covering the walls of rooms with poisonous paper? It is obvious that everybody exposed to the influence in question is not affected, even to a moderate degree. No positive criterion can be established, indeed, since the conditions of exposure are so varied and complicated. It cannot be said of a sample of wall-paper with a stated amount of arsenic on its surface, that when laid on the wall of a room it will produce a regular series of

* "Toile métallique."

† "La mordance en alumine."

‡ From the "Third Annual Report of the State Board of Health Massachusetts."

symptoms in the persons occupying the room a given length of time. Other things being equal, the persons whom habit or occupation keeps much within doors would be most likely to suffer, and we should look for most numerous cases among women and young children. But, in point of fact, we find a great diversity of susceptibility. Among those who are even exposed continuously to the action of the poison, there occur instances of immunity. Such a case is cited by Dr. Guy:—

"I have myself known an instance of a spacious day and night nursery opening into each other, and covered with a flowered paper rich in emerald green, occupied for several months together by nurses and children, and yet without in any way affecting the health of the inmates. The poison in this case was so loosely laid on that it deeply stained a white handkerchief rubbed over it. This case is the more striking as it occurred in the house of a physician well acquainted with the effects of the poison and quite alive to their detection."

But these negative cases are important only as showing the tolerance of a poison by the human system, and they do not annul the force of such testimony as has been quoted. It is a fact well recognised by physicians that different organisms vary exceedingly in their susceptibility to the action of drugs, and this idiosyncrasy will explain much of the diversity of effects observed in connection with the mode of chronic arsenical poisoning we are studying. An agent which is comparatively inert as regards one organism is to another an active poison. But because, for example, the poisonous ivy is to some persons harmless, or because certain people in Styria can swallow pure arsenic and appear to thrive upon it, there will yet be few of us who, knowing the possible results to ourselves in the one case or the other, would be quite willing to purposely test our own powers of tolerance. It is hardly justifiable, therefore, to put children to sleep in an atmosphere charged even slightly with arsenic, voluntarily trusting to the chances that such an exposure will be harmless.

When to this consideration of susceptibility are added other conditions, such as the previous health of persons, the degree of exposure (depending, primarily, on the amount and tenacity of the arsenic in the paper, and indirectly on attention to ventilation), or the eliminating power of the system, it will be seen how many circumstances influence the effect of the poison. Few will be found who, with any knowledge of the facts, will insist that a mineral agent which is capable, almost invariably, of producing well-recognised effects when taken into the stomach, is as invariably incapable of harm when it is more indirectly absorbed by the system through the mucous membrane of the respiratory organs; and few will be ready to take on themselves the voluntary risk of testing the question in their own persons by habitually dwelling in arsenical rooms, or will think it advisable that any human being should breathe the poisoned air of such rooms, even admitting that a portion of mankind is, in this respect, arsenic-proof.

The idea readily suggests itself that, if such effects as those described are to be observed in the occupants of rooms decorated with green paper, we ought certainly to discover some influence on the health of workmen who are exposed to the action of the arsenical pigments in the practice of their trades; and we should look for positive testimony from those engaged in the manufacture of the paper-hangings and from those who put the papers on the walls of rooms. And evidence of this kind is not wanting. The investigations of Chevallier, of Pietra-Santa, of Dr. Guy, and others show that a distinctive train of symptoms appears in those habitually engaged in making arsenical papers, and that these symptoms are referable to the arsenic in the pigment. According to these authorities, they are not unlike those already enumerated as observable in the occupants of arsenical rooms; they consist of thirst, nausea and vomiting, pain in the stomach

and bowels, great prostration, disturbances of digestion, drowsiness, headache, nervous tremblings, and (traceable more directly to the local action of the arsenic) sore throat and irritation of the mucous membrane of the nose and mouth, showing itself in sneezing, a mucous or bloody discharge and swelling of the lips. Coincident with these is the appearance sometimes of various eruptions on exposed parts of the body, as the hands and face. These eruptions are sometimes mere pimples, sometimes they resemble erysipelas (erythematous), and sometimes they develop to ulcerations whose favourite seat is in the folds of the fingers and about the roots of the nails, where the pigment would be most likely to make a more or less permanent lodgment. These symptoms manifest themselves with a severity and uniformity in proportion to the degree, length, and continuity of exposure, to the workman's neglect of cleanliness, and to individual susceptibility to the poison; and they disappear spontaneously when the work in green colours is discontinued. The personal researches of the writer verify many of these observations.

Many paper-hangers, likewise, recognise the fact that certain green papers have a tendency to develop a peculiar set of symptoms in those engaged in fitting and hanging the paper on the walls of dwellings. These symptoms are of an acute character, manifesting themselves without delay and giving evidence of a local effect. They resemble, in many respects, those which characterise the beginning of an ordinary "cold in the head," and consist of sneezing, irritation of the eyes and nostrils, headache, and swelling of the lips; in the more severe forms of poisoning, there is vomiting, with diarrhoea and an indescribable feeling of illness. Many cases of this kind have been reported from time to time, and some instances are recorded in which the paper-hangers have asserted that they never could work upon certain green papers without being made seriously ill. In the course of this investigation, the writer has obtained information from paper-hangers which in many respects corroborated the observations recorded. Of nine of these men who were seen, seven had been poisoned by the arsenical wall-paper with various degrees of severity; the two negative cases were those of men who had not been long engaged in the business. Of the seven instances, one was especially marked. Within twelve hours after working upon a paper whose pigment was loosely laid on, the symptoms of poisoning showed themselves; there was irritation of the mucous membrane of the eyes, nose, and mouth, accompanied with great prostration of strength; presently, an eczematous eruption appeared on the hands and extended to other parts of the body. The illness was so severe as to necessitate entire suspension of his work, and he entered the hospital for treatment.

In the other cases, the symptoms were less serious, but they were sufficiently characteristic. Immediately consequent upon the work with the emerald-green papers, and disappearing within a week after the exposure ceased, the effects before described were experienced,—inflammation of the eyes (conjunctivitis), swelling of the nose with a mucous discharge, ulcerations about the nostrils, headache, sore lips, and sometimes bleeding from the nose.

The following instance has incidentally come to the writer's notice. Mr. W., a young man of robust constitution, a salesman in a paper-hangings store, complained of nausea, diarrhoea, great lassitude, inflammation of the conjunctiva, mucous discharge from the nose, and occasional dizziness. The symptoms could be explained by no unusual excess or exposure, and nothing was elicited to which his condition could be attributed save the fact that during the month previous he had exhibited to customers more patterns of arsenical green paper than usual.

To these statements concerning the ill effects experienced by workmen, exception will be taken by some, and especially by those interested in the manufacture and sale

of paper-hangings, on the ground that none of the alleged injuries have occurred under their observation. It may readily be seen that, notwithstanding its apparent partiality, such negative testimony might be given in all sincerity. The symptoms described are such as would naturally be referred to other causes; they are, in a measure, obscure; they occur with exceptional severity and they do not terminate fatally; they do not generally interfere with the performance of duty, and a workman would not be likely to complain of a condition of things of whose real character he had no certain knowledge, especially when he was dependent on his occupation for a livelihood.

This study of the employment of the arsenical-green pigments in various arts, and of the manifold noxious effects which directly or indirectly result, suggests, in conclusion, the consideration of some remedy for what we must term an evil. There will, of course, be those who will hesitate to condemn this use of arsenic, and who will hardly be ready to denominate it an evil. To those, for example, who regard fatality, the aggregate number of deaths, as the test by which the fruits of an alleged abuse are to be relatively judged, this whole inquiry will appear unnecessary, perhaps unjustifiable.

Not so do those reason who have themselves observed the ill consequences of too great trust in colour, or who have experienced those effects in their own persons. Those who realise that seriously impaired health does, in a certain number of cases, surely result from the employment of an active poison in the composition of a colour whose sole purpose is as a luxury to gratify the sense of vision, and which has not the smallest claim as a necessity, feel that an emphatic word of warning is imperative. It is to be remembered that the arsenical colours are poisons scarcely less active than the agent which gives them their name; and being colours simply, a single unequivocal instance of injury justifies their condemnation without the need of waiting until people are habitually killed by them.

Many suggestions have been made with the view to the protection of people from the harmful effects resulting from the arsenical greens. For example, the green wall-papers are to be covered with a layer of varnish; the workmen are to be specially instructed with regard to cleanliness; and so on. At best, these are but compromises and a partial remedy; and were it carried out as fully as practicable there would still be abundant exposure. If the use of arsenic in the relations we have studied is an evil, it is an absolute evil, concerning which the public may well be informed, for "the people perish for lack of knowledge" of the risks to which they unconsciously expose themselves in the means they take to gratify a refined taste for the beautiful.

If there can be awakened in the community some appreciation of the dangers which belong to the indiscriminate use of emerald-green colours, there will be no need to invent methods of repression in behalf of the public health; for reasonable people, informed concerning the risks, will not be likely to test their own tolerance of arsenic or to subject their children to it. The demand ceasing, the supply will cease; and a correct taste in colour will find its gratification in agents which possess no poisonous character.

LABORATORY NOTES.

TO CUT AND BORE INDIA-RUBBER CORKS.

DIP the knife, or cork-borer, in solution of caustic potash or soda. The strength is of very little consequence, but it should not be weaker than the ordinary reagent solution. Alcohol is generally recommended, and it works well until

it evaporates, which is generally long before the cork is cut or bored through, and more has to be applied; water acts just as well as alcohol, and lasts longer. When, however, a tolerably sharp knife is moistened with soda-lye, it goes through india-rubber quite as easily as through common cork; and the same may be said of a cork-borer, of whatever size. I have frequently bored inch holes in large caoutchouc stoppers, perfectly smooth and cylindrical, by this method. In order to finish the hole without the usual contraction of its diameter, the stopper should be held firmly against a flat surface of common cork till the borer passes into the latter.

The above may not be new—in fact, the chances are greatly against it; but it will, I think, be new to at least as many of your readers as the instructions, abstracted in the June number of the *Journal of the Chemical Society*, for adapting tubes of different sizes to one another.

W. F. DONKIN.

NOTICES OF BOOKS.

Michael Faraday. By J. H. GLADSTONE, Ph.D., F.R.S. London: Macmillan and Co. 1872.

THIS is a work which we notice with almost a reverence because of its subject. Faraday—the name alone calls to mind the picture of the philosopher, great in his simplicity—may be said to have inspired his biographers with such an affection, yet a touching sorrow, in their work, that the account of his life, whether written by either of the Professors De la Rive and Tyndall, or by either Drs. Bence Jones and Gladstone, is interesting even to those to whom chemistry and Faraday are unknown. We have in the present work by Dr. Gladstone much additional information, many unpublished incidents truly characteristic of the great philosopher. "His method of working" as analysed by Dr. Gladstone should be read by every chemist.

Contributions to Molecular Physics in the Domain of Radiant Heat. By JOHN TYNDALL, LL.D., F.R.S., Professor of Natural Philosophy in the Royal Institution. London: Longmans, Green, and Co. 1872.

THIS is a reprint of the series of Dr. Tyndall's memoirs published in the *Philosophical Transactions* and *Philosophical Magazine*. Much has been added, and to each memoir has been prefixed an analysis of its contents, from which the reader can at once learn the nature of the inquiry. This volume contains the conclusion of the discussion between Professor Magnus and Dr. Tyndall as to the action of air, and that of aqueous vapour upon radiant heat. The general reader who has mastered Dr. Tyndall's more popular work on the subject of heat, will find the present issue of much interest and high value.

Magnetism and Deviation of the Compass. By JOHN MERRIFIELD, LL.D., F.R.S. London: Longmans, Green, and Co. 1872.

THE changes in the examinations conducted by the Board of Trade have produced among candidates the want of a small manual, embracing the necessary information on magnetism and deviation of the compass, and which should be adapted to the capacity of the student. This want is in this manual most admirably fulfilled, and the thanks of all students of navigation are due to Dr. Merrifield for his clear and easy exposition of the difficulties and anomalies attending the subject of compass deviation, more particularly in the case of iron ships, and of the principles of the science of magnetism.

CORRESPONDENCE.

ARSENIC IN COLOURS.

To the Editor of the Chemical News.

SIR,—Reading in your columns Dr. Draper's article "On the Evil Effects of the Use of Arsenic in Certain Green Colours" brought to my recollection the examination of some pigments other than greens which contained arsenic.

The pigments were of French manufacture and said to be used in calico printing, and were sent here for trial, and rejected for two reasons—(1) because of the large quantity of arsenious oxide present; (2) because colours equally good could be obtained on calico by other methods, without the use of that dangerous substance and at less expense. The names were as follows:—

Light scarlet pigment.—Contained alumina, arsenious oxide, and aurine.

Scarlet ponceau.—Contained carbonate of lime in addition to above ingredients.

Dark green.—A preparation of aniline green and arsenious oxide.

Steam chocolate and catechu pigment.—Both contained arsenious oxide.

Now, as these lakes were very brilliant, I have no doubt they would be found suitable for paper-hangings. The arsenious oxide is not at all necessary for the production of the lake, but is used, I believe, solely for the purpose of giving body to the pigment.

My object in writing is to warn chemists of the necessity of examining for arsenic the bright scarlets, reds, and other pigments found in paper-hangings, as well as the greens.

I have no positive information as to whether any of these colours have actually been used for paper-hangings or not; but as such are undoubtedly prepared and to be had in the market, I have no doubt they will be sooner or later used for that purpose; in fact, I have recently seen, in an extract from a German journal, that Dr. Hallwachs had found arsenic in red paper-hangings.—I am, &c.,

J. WALLACE YOUNG.

Springfield Printworks, Glasgow.

DISEASED POTATOES.

To the Editor of the Chemical News.

SIR,—It may interest some of your readers to know that sulphite of lime appears to exercise a very remarkable influence in arresting the spread of the decay in potatoes affected by the disease now so prevalent.

In one experiment, this salt (which has been long applied in preserving meat) was dusted over some tubers, partly sound and partly affected, as they were being stowed away. Some months afterwards, the potatoes were found to have suffered no further injury. A comparative trial with powdered lime was much less successful.—I am, &c.,

A. H. CHURCH.

Royal Agricultural College,
Cirencester.

ESTIMATION OF NITRATES IN POTABLE WATERS.

To the Editor of the Chemical News.

SIR,—At the time of writing a letter to the CHEMICAL NEWS "On the Estimation of Nitrates in Potable Waters," which appeared a short time ago, I had not seen the excellent work on "Water Analysis," by Messrs. Wanklyn and Chapman, having practised their process from their original papers to the Chemical Society, and from the account of it given in Watts's "Dictionary;" I was not, therefore, aware that they had given a method almost exactly similar to that proposed by me, and I lay under

the impression that no previous suggestion had been made to utilise the Nessler test in the estimation of nitric acid. I shall feel much obliged by your inserting this note.—I am, &c.,

THOMAS P. BLUNT.

The Wyle Cop, Shrewsbury,
August 23, 1872.

MISCELLANEOUS.

British Association for the Advancement of Science.

—The number of tickets issued at the Brighton Meeting was as follows:—Old life members, 245; new life members, 360; old annual members, 280; new annual members, 80; associates, 937; ladies, 912; foreign members, 43; total number of tickets, 2,533, representing £2,649.

Chemistry in Italy.—There are no handbooks on chemistry in the Italian language; but a work has been in course of publication since 1867 somewhat similar to the first edition of the celebrated German "Handwörterbuch der Reinen und Angewandten Chemie," viz., "Enciclopedia Chimica," edited by F. Selmi, of Bologna, with the co-operation of Arnaudon, of Turin, for technical chemistry, and of Sestini, Paterno, and others for pure chemistry. There are 2000 subscribers to this work, which is highly valued in Italy. The Italian Government has appointed Dr. Canizzaro, Professor of chemistry at Rome; and £20,000 has been voted by the Italian parliament for the establishment of a chemical laboratory in Rome. The Florentine Institute (*Istituto Superiore*) receives, in addition to its present subsidies, an annual subsidy of £25,000, and will be converted into a kind of Polytechnic University.

Plumbago.—The value of plumbago, or graphite, depends on its amount of carbon. In order to ascertain this, the simplest and best method is to dry the pulverised graphite at a temperature of some 360° F., and then place it in a tube, 4 to 5 inches long, and half an inch wide, made of hard glass and closed at one end. To this is added about twenty times as much well-dried oxide of lead, and the whole is well mixed. The tube is then first weighed, and afterwards heated before the blowpipe till the contents are completely effused and no longer evolve gases. After this operation, which does not last longer than ten minutes (if the quantity is not too large), the tube is allowed to cool, and its weight is again ascertained. The loss in weight is carbonic acid, the oxygen of which has been taken from the lead oxide, while the carbon is all that there was in the plumbago. For every 28 parts of loss, there must have been 12 of carbon. In general, it is sufficient to take from 1 to 2 grms. of plumbago, and from 20 to 40 of oxide of lead.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Stances de l'Académie des Sciences, August 19, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

Action of Ozone upon Sulphate of Indigo and upon Arsenious Acid.—A. Thenard and P. Thenard.—This essay records the results of a series of experiments made to ascertain, if possible, the real

nature of ozone. The quantity of ozone required to oxidise arsenious acid is equal to the quantity of oxygen required for the same purpose; it appears that ozone oxidises three times as much indigo as permanganate of potassa and other oxidising substances; it has, moreover, been found by the authors that with ozone there is a continuous action, which they consider due to the formation of peroxide of hydrogen.

Investigation of the Meteorites which Fell on July 23 last at Lancé and at Authon (Loir et Cher).—M. Daubrée.—One of these minerals weighs 47 kilos. The results of the author's analysis are the following, in 100 parts:—Free iron, alloyed with nickel and cobalt, 7.81. Iron and other metals (including a small quantity of copper, detected by spectrum analysis) combined with sulphur, 9.09; combined sulphur, 5.19; together, 14.28. Silicates acted upon by acids—Silica, 17.20; magnesia, 13.86; protoxide of iron, 11.33; protoxide of manganese, 0.05; together, 42.41. Portion insoluble in acids, 33.44; chloride of sodium, 0.12; hygrometric moisture, 1.24.

Action which Silica and some Analogous Oxides Exert upon Carbonate of Soda at a High Temperature.—M. Mallard.—The main gist of the contents of this memoir is that when silica, SiO_2 , titanate acid, TiO_2 , and zirconia, ZrO_2 , are brought into contact with carbonate of soda, and strongly heated, the quantity of carbonic acid disengaged tends to a certain limit which it is impossible to overcome, and which increases with an increase of temperature. The author explains this by the mutual action of the bisilicate upon the proto-silicate, comparing the phenomenon to the decomposition observed by Berthelot of the acid salts of the dibasic acids when in solution.

Bequest to the Academy.—Dr. J. Dumas.—As one of the Perpetual Secretaries, the eminent *savant* communicates that the late Field-Marshal Vaillant has bequeathed to the Academy a sum of 40,000 francs, the interest of which is to establish a biannual prize for any subject the Academy thinks fit to select.

Compressibility of Hydrogen and Air at High Temperatures.—M. Amagat.—The author describes at length his method of experimenting, and quotes the following results:—

	Air.	Hydrogen.
At 100°	1.00011	
At 250°	1.00025	0.99986
At 320°	1.00018	—

Division of One Base between Several Acids while in Solution; Bibasic Acids.—Dr. Berthelot.—The continuation of a series of memoirs on this subject; this portion is elucidated by several tables.

Tendency of Certain Gases to Obtain Permanently-Active Properties Under the Influence of Electricity.—M. Chabrier.—This memoir contains the detailed account of the author's researches concerning hydrogen, which, when electrified by means of Houzeau's ozoniser, was found to combine directly with nitrogen, forming ammonia; this hydrogen was also found to decompose freshly-made oxide of silver, metallic silver being formed, and so much heat was evolved that the metal melted, although the experiment took place at the ordinary temperature of the air.

Artificial Production of Pyroxen and Peridot.—G. Lechartier.—This essay records the results of the author's experiments, made with the view of artificially producing the minerals known as pyroxen and peridot; full details of the quantities of the constituents of these minerals to be mixed and of the mode of operation are given.

This number also contains important original papers relating to astronomy, meteorology, geology, physiology, and natural history.

Le Moniteur Scientifique Quesneville, No. 368, August, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

On Pulmonary Respiration and on Animal Heat.—Ch. Blondeau.—A lengthy chemico-physiological monograph on this subject.

Chemical Researches on Condurango.—G. Vulpinus.—There are two drugs of this name met with in commerce; one of these, which has been known for the last ten years, generally termed *guaco*, consists of the cut-up branches and young twigs of the *Miconia guaco*, a native of Venezuela; the other, the subject of this memoir, is obtained from Chili, but the plant or tree it is derived from is at present not well known. The author found, in the sample he investigated, 12 per cent of a white-coloured ash, of which 16.7 per cent was soluble in water. The bark was treated first with ether, yielding 5.2 per cent of dry ethereal extract; with alcohol, the residue of this operation yielded 8.94 per cent of dry alcoholic extract. This residue was then treated with water, yielding 1.13 per cent of dry aqueous extract; on treating this residue with dilute hydrochloric acid (1 part of pure HCl and 19 parts of water) the author obtained, on evaporation of the chloroform solution of a lime precipitate, a small quantity of a resinous matter, while a further treatment of the residue of the bark, with a weak (5 per cent) caustic potassa solution, yielded no active principle, as regards the bark; the author considers this is due to the presence therein of two resinous compounds, which in concentrated state are best obtained in the form of tincture or alcoholic extract, by means of very strong alcohol. According to Dr. Triana, the condurango, more correctly *cundurango*, is the bark of the *Gonolobus cundurango*, a tree met with in several regions of South America.

Anthracen and its Derivatives.—Dr. E. Kopp.—The continuation of an exhaustive monograph on this subject, this portion being divided into the following sections:—Properties of alizarine; alkaline alizarates; alizarate of ammonia, and alizaramide or alizaréine.

Isopurpurine Extracted from Artificially-Prepared Alizarine Obtained from Gessert Brothers, at Elberfeld.—Dr. Auerbach.—From the crude substance (artificially-prepared alizarine) the author obtains the isopurpurine, by first treating the raw material with a dilute solution of caustic alkali, and precipitating with chloride of calcium; the coloured lime-lake thus formed is treated with boiling water until it ceases to be coloured; this fluid is precipitated with hydrochloric acid, and the precipitate again converted into a lime-lake, an operation to be repeated several times in order to completely eliminate the alizarine. The pure substance, obtained by the aid of re-crystallisation from an alcoholic solution, is soluble in caustic soda, the solution exhibiting an orange colour; its chemical composition, in 100 parts, is—C, 70.76; H, 3.57; O, 25.67. In many of its properties it resembles anthraquinic acid, but isopurpurine is not identical with purpurine, although the two substances agree as regards the dyeing of mordanted cotton.

C. A. de Nativelle's Crystallised Digitaline.—Dr. Quesneville.—This lengthy memoir treats exhaustively on the subject of crystallised digitaline, reviewing the labours and researches of Latour, Gubler, Homolle, Nativelle, and others, as regards physiological experiments and chemical investigations.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, June 9, 1872.

Artificially-Made Butter.—Mége-Mouriez.—Some years ago the author was requested by the Viçualing Department of the French Navy to try to find a wholesome substitute for butter, which would not become rancid by keeping. Experiments made with cows, submitted to a very severe and scanty diet, led to the discovery that these animals continued to give milk, although in very much smaller quantity, and that this milk always contained butter; the author surmised that this butter was due to the absorption of the fat contained in the animal tissues, which was converted into butter under the influence of the milk-secreting glands. This led to experiments on the splitting up of animal fats, and, further, to the following process for making butter artificially. Best fresh beef-suet is first mechanically cut up, by means of circular saws fitted to a cylinder, and is next placed in a vessel containing water, carbonate of potassa, and fresh sheep's stomachs previously cut up into small fragments; the temperature of this mixture having been raised to 45°, the joint influence of the pepsine of the stomachs and heat causes the fat to be separated from the cellular tissue; the fatty matter floating on the top is decanted, and, after cooling, submitted to very powerful hydraulic pressure; the stearine is used in candle-making, and the semi-fluid oleomargarine is used for making the artificial butter in the following manner:—50 kilos. of the fat are poured, along with 25 litres of milk and 20 litres of water, into a churn, while there is added 100 grms. of the soluble matter obtained by soaking for some hours in milk from cows' udders and milk-glands; a small quantity of annatto is also added, and the operation of churning then proceeded with. The butter thus obtained is well washed with cold water, and, if required to be kept for a long time, melted by a gentle heat, to eliminate all the water. According to reports of sanitary committees, as well as of the authorities of the Viçualing Department of the French Navy, this artificial butter is really an excellent substitute for genuine butter, and can be exposed for sale if the vessels are marked to distinguish the artificial from the genuine butter.

Hydraulic Blowpipe and Aspirator-Apparatus for Chemical Laboratories.—Dr. H. Sainte-Claire Deville.—This memoir, illustrated by woodcut, contains the detailed description of an apparatus, the principle of action of which is based upon the well-known Catalan blowing-machine. By the arrangement here described, a very powerful blast can be obtained, as well as an aspirator-apparatus, which are constructed by M. Wiesnegg at Paris, the cost, with accessories, being about £5.

Manure for Beet-Roots and other Crops.—Crespel and Co.—In order to withdraw the free sulphuric acid from the beet-root vinasse, the authors add carbonate of baryta, and, when no more effervescence ensues, the precipitated material is drained, and next pressed by means of hydraulic presses; this product constitutes the manure, which, according to an analysis of Professor Violette at Lille, contains, in 100 parts—Nitrogen, 1.42; non-nitrogenous organic matter, 20.31; phosphate of lime, 1.50; sulphate of lime, carbonates, and alkaline salts, 11.32; sand, clay, &c., 65.45. This manure has been found to answer well for beet-roots, and is cheap.

Manufacture of so-called Porcelain Buttons.—C. Mène.—The detailed description of a process of making a peculiar kind of ceramic paste, which is moulded into buttons; felspar, sulphate of lime, phosphate of lime, and other minerals are used in this industry, which is carried on, it appears, on a large scale in some districts of France.

Pharmaceutische Zeitschrift für Russland, No. 4, 1872.

This number contains no original papers relating to chemistry.

No. 5, 1872.

Description of an Apparatus Contrived with the View of Regulating Gas- and Spirit-Lamp Flames so as to keep up a Fixed Temperature for a Length of Time.—Dr. J. Martenson.—This paper is illustrated by a woodcut.

Nomenclature of the Alcohol Radicals.—J. Biel.—After referring to the inconvenience of the prefixes pseudo, iso, and pseudo-iso, and also to the difficulty arising from the use of expressions such as butylen from erythrite, butylen from allyl, and butylen from

trimethyl-carbinol, the author proposes that the use of α , β , γ , δ , &c., shall be applied to the hydrocarbon radical, as well as to the corresponding alcohol and the acid belonging to the same radical; as instances, the following isomers of amyl, amylic alcohol, and capronic acid, are quoted:—

Hydrocarbon Radical.	Corresponding Alcohol.	Capronic Acid containing the same Radical.
(1). α amyl, butylated methyl.	α amylic alcohol, normal primary amylic alcohol.	
(2). β amyl, dimethyl propyl.	β amylic alcohol, fermentation amylic alcohol, primary amylic alcohol.	β capronic acid prepared from cyanide of amyl.
(3). γ amyl, ethylomethylated ethyl.	γ amylic alcohol, unknown primary amylic alcohol.	
(4). δ amyl, trimethyl ethyl.	δ amylic alcohol, unknown primary amylic alcohol.	
(5). ϵ amyl, diethylated methyl.	ϵ amylic alcohol, unknown secondary amylic alcohol.	ϵ capronic acid, diethylacetic acid.
(6). ζ amyl, methylopropylated methyl.	ζ amylic alcohol, secondary amylic alcohol, isoamylic alcohol.	
(7). η amyl, methylo-pseudopropylated methyl.	η amylic alcohol, secondary pseudo-amylic alcohol, amylen hydrate.	η capronic acid from amylen hydrate.
(8). θ amyl, dimethyl-ethylated methyl.	θ amylic alcohol, tertiary pseudo-amylic alcohol.	

Nos. 6 and 7, 1872.

These numbers contain the following original paper relating to chemistry:—

Platinocyanides and Tartrates of Beryllium.—Dr. F. Tockzynski.—This exhaustive monograph is divided into the following sections:—Preparation and analytical characters of beryllium oxide; platinocyanides of beryllium; cyanide of beryllium; ferrocyanide of beryllium; ferricyanide of beryllium; rhodan-beryllium; nitroprussid-beryllium; beryllium platinocyanide; beryllium-magnesium platinocyanide; tartrates of beryllium; potassium-monoberyllium tartrate; potassium-diberyllium tartrate; stibium-monoberyllium tartrate; stibium-sequi-beryllium tartrate; formulae of the double tartrates of beryllium—

Tartaric acid	$C_4H_4O_6$
Bitartrate of potassa	$C_4H_4O_6$
Potassium-diberyllium tartrate	$C_{12}H_8K_2Be_2O_{18}$
Potassium-monoberyllium tartrate	$C_{12}H_8K_2Be_2O_{18}$
Werther's copper salt	$C_{12}H_8H_2Na_2Cu_4O_{18}$
Stibium, or antimonium-sequi-beryllium tartrate	$C_{12}H_8H_2Be_2Sb_2O_{18}$
Antimonio-tartrate of potassa	$C_{12}H_8H_2K_2Sb_2O_{18}$

No. 8, 1872.

This number contains no original papers relating to chemistry.

No. 9, 1872.

The only paper relating to chemistry in this number is—

Relation of Modern Chemistry to Metallurgy.—Dr. C. Winkler.—The first instalment of a monograph written with the view of rendering the study of modern chemistry more in harmony with the practice of metallurgy. Speaking of hydrogenium, the author states that in the solid state it is a white-coloured, magnetic, rather tough metal, of about 0.733 sp. gr., and a good conductor of electricity.

Les Mondes, August 22, 1872.

French Association for the Advancement of Sciences.—The first meeting of this Association will be held from the 5th to 12th of September next in the City of Bordeaux. There will be two general meetings, sectional meetings, public conferences, and scientific excursions extending to the Departments of the Landes, Gers, Gironde, and Charente Inférieure, with the view of visiting important industrial works, parks in which oysters and sea-fish are cultivated, vineyards, open air magnaneries, salt and iron mines. Among the subjects on which public lectures will be given we notice the following:—Constitution of the sun; troglodytes of Eysies; commercial geography; exploration journey of the Camboage; and the politico-commercial influence of France in the far East. The Association already possesses a capital of upwards of £5000, a sum which it is expected will soon be greatly increased.

International Congress of Weights and Measures.—This congress, to which delegates from almost all European countries are expected to attend, will be held at Paris on the 24th of September next. The main point to be discussed will be the adoption, if possible, of a uniform international system of weights and measures, in order to obviate the difficulties experienced by commerce from the want of such a system in Europe.

Active Hydrogen.—M. Chabrier.—The author has discovered that, when hydrogen is electrified by an electric discharge, and not attended with sparks, it then directly combines with nitrogen, forming ammonia. Under the same conditions, hydrogen decomposes freshly-made oxide of silver; and so much heat is evolved by this operation that the globules of metallic silver melt, and in a state of high incandescence take up oxygen, which, on cooling, is given off, producing the well-known phenomenon also observed in the silver assay by the dry way.

Freezing of Water.—C. Tellier.—It is generally admitted that water freezes at 0° , and can only be cooled down below its freezing-point by being kept perfectly tranquil. This holds good for a cold of -10° or -12° , but is, according to the author, not true for temperatures of -3° or -4° ; because water may be cooled down to these degrees of temperature, and will not freeze even when the vessel containing it is very violently shaken or stirred. Only a sudden and very violent shock to the vessel will cause the water to become frozen, the temperature rising to 0° ; but if, in water cooled down to -3° or -4° , the slightest particle of ice or snow is put, congelation briskly sets in and crystallisation ensues, just as in a supersaturated solution of sulphate of soda. Practically, this observation is important, as it proves the necessity of water containing ice if it is desired to cool it down to 0° precisely.

Modifications of the Electric Machine.—L. Brunelli.—The description, illustrated by engravings, of an arrangement whereby the electric machine is rendered more effective and powerful.

Asbestos for Use in the Stuffing-Boxes of Steam-Engines.—M. Day.—It appears that asbestos is an excellent and durable substitute for hemp or flax in the stuffing-boxes of steam-engines, because asbestos better resists the joint action of friction, humidity, and high temperature.

Saltpetre in South America.—Rev. F. Moigno.—The author states that, according to a low calculation, there is at Tamarugal alone, where the nitre beds extend over 483 square miles, a quantity of saltpetre equal to 63,000,000 tons, sufficient at the present rate of consumption for 1393 years, while larger quantities of this salt are known to exist at the foot of the Cordilleras.

Journal de Pharmacie et de Chimie, August, 1872.

In addition to several papers relating to pharmacy, this number contains the following:—

General Method of Immediate Organic Analysis.—Dr. Fleury.—The continuation of a monograph on this subject, this portion being divided into the following sections:—Investigation of aqueous fluid; treatment with alcohol.

Sulphhydrate of Chloral (Sulphuretted Chloral).—H. Byasson.—When anhydrous chloral is acted upon by sulphuretted hydrogen, there is formed, while a very perceptible amount of heat is evolved, sulphhydrate of chloral, a solid white-coloured body, which is soluble in ether, in anhydrous alcohol, and chloroform, and may be obtained from these solutions in crystalline state; this substance fuses at 77° , and boils at 123° ; water decomposes it, the result being the formation of sulphuretted hydrogen, which escapes, while the fluid contains hydrochloric acid and hydrate of chloral in solution. Under the influence of hydrated alkalies and ammonia, it is rapidly decomposed; there are formed sulphhydrates of the alkaline metals, as well as formiates and chlorides of the bases. Nitric acid violently decomposes sulphhydrate of chloral, while cold concentrated sulphuric acid has no action upon that substance, but, when hot, sulphuric acid converts it into hydrate of chloral, sulphuretted hydrogen and sulphurous acid being evolved.

Aspect of Milk Seen Under the Microscope before and after Churning and Creaming it.—M. Boussingault.—This paper, illustrated with engravings, contains some important observations on the operation of churning. It appears that from 100 parts of milk, containing 40.4 of butter, only 29.5 were obtained by churning, leaving behind in the butter-milk 10.9 parts; milk which is creamed under the most favourable conditions yet retains from 0.3 to 0.4 per cent of butter. By means of the microscope, cream, skim-milk, butter-milk, and whey may be perfectly well recognised.

Some Compounds of Paraffin.—M. Champion.—When paraffin is kept for sixty hours at 90° , in the presence of nitrosulphuric acid, there is formed (while copious vapours of nitrous acid are evolved) a fluid of 1.14 sp. gr. at 15° , which is insoluble in water, but soluble in alcohol, ether, and amylic and methylic alcohols. This compound combines with alkalies, and has been termed paraffinic acid, $C_{26}H_{54}NO_{10}$. Ethyl, methyl, and amyl compounds of this acid have been obtained by the author; the formula of the ethyl compound is $C_{26}H_{54}(C_2H_5)_2NO_{10}$.

Journal für Gasbeleuchtung und Wasserversorgung, No. 12, 1872.

This number contains, in addition to several original papers strictly relating to gas- and water-works' engineering, a paper—

Purification of Glycerine which has been Used in Gas-Meters.—M. Hasse.—After stating that at Dresden glycerine is generally used in gas-meters, the author gives a detailed account of a process for purifying the glycerine after it has been some four years in the meters, so as to render it fit for use again. The fluid is first heated for twelve hours to from 50° to 60° , and next to from 120° to 130° in order to eliminate water, ammoniacal compounds, and other volatile impurities; the glycerine is next filtered over granulated animal charcoal. Some 300 to 400 cwts. of glycerine are annually purified in this manner at Dresden.

NOTES AND QUERIES.

Dryer for Tarry Substances.—(Reply to C. E.)—Your best plan to obtain a quickly-drying tar is to boil it, and apply it hot; and if expense is not an object, add some Trinidad asphalt or bitumen to it while boiling.

Manufacture of Iodine.—(Reply to "Medicus.")—In Mr. Crookes's edition of Wagner's "Chemical Technology," published by Messrs. Churchill, there is a complete account of the preparation of iodine from kelp and from the mother-liquors left by crude nitrate of soda and common sea-salt manufacture.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents, 54, Chancery Lane, London, W.C.

NOTICES TO PROCEED.

1044. W. R. Lake, Southampton Buildings, London, "Improvements in the manufacture of pulp from vegetable fibres for making paper and other materials."—A communication from G. Swift, San Francisco, California, U.S.A.—Petition recorded April 8, 1872.
1054. E. Sonstadt, Ramsey, Isle of Man, "Improvements in the manufacture of iodide of potassium and bromide of potassium."—Petition recorded April 10, 1872.
1088. W. R. Lake, Southampton Buildings, London, "An improved process of converting cast-iron and articles made thereof into steel."—A communication from H. H. Date and J. F. Date, St. Catherine's, Ontario, Canada.—Petition recorded April 12, 1872.
1103. R. Tierman, Liverpool, "An improved manner of treating tobacco."—Petition recorded April 13, 1872.
1265. E. A. Cowper, Westminster, "Improvements in the process of converting wood and other fibrous materials into pulp, and in apparatus therefor."—Petition recorded April 27, 1872.
2279. J. Brown, Edinburgh, N.B., "Improvements in the treatment of sewage and in the manufacturing of manures."—Petition recorded July 30, 1872.

PATENTS GRANTED IN BRITISH COLONIES.

TRINIDAD.

FROM THE YEAR 1852 TO THE YEAR 1867, BOTH INCLUSIVE.

- J. Ramos, "A process for the better classification of the expressed juice of the sugar-cane while being manufactured into sugar." (1852).
- J. Brandeis, "Certain improvements in the manufacture and refining of sugar." (1853).
- A. W. Anderson, "Certain improvements in the manufacture of sugar." (1853).
- A. A. L. Cochrane, "Certain improvements in the use of the bitumen of this colony in the manufacture of fuel." (1854).
- H. Hyde, "Certain improvements in the preparation of mineral oils." (1856).
- S. R. Philbrick, "A new apparatus for distilling the asphalt of this island, and a new process for obtaining an illuminating oil from the asphalt of this island, or the distillates of such asphalt." (1857).
- H. S. Warner, "Certain improvements in preparing de-colouring charcoal." (1857).
- H. S. Warner, "Certain improvements in preparing asphaltic fuel." (1859).
- H. Mitchell, "A new apparatus for distilling the asphaltum and other naphthaline exudations of this island, and also a new process for obtaining greasy or oily products from the asphaltum of Trinidad, or the distillates of such asphaltum." (1859).
- C. F. Stollmeyer, "Certain improvements in preparing and combining diverse materials to form a strong and concentrated manure." (1859).
- H. W. R. Ellis, "An improvement in the manufacture of sugar." (1860).
- H. W. R. Ellis, "An improvement in the distillation of rum." (1860).
- H. S. Warner, "Certain improvements in furnaces, and in the treatment of megass as fuel." (1860).
- A. L. Le Roy, "Certain apparatus for and improvements in the preparation of megass for use as fuel." (1861).
- The Earl of Dundonald, "Certain improvements in obtaining products from coal, gas tar, gas pitch, asphalt, resin, and other bituminous and resinous substances." (1861).
- P. Rostaat, "Preparation of megass for use as fuel." (1861).
- The Earl of Dundonald, "An improved mode of concentrating and purifying asphalt or bitumen." (1862).
- P. Rostaat, "The preparation of megass for use as fuel." (1863).
- A. L. Pozzo, "Improvements in the manufacture of sugar." (1863).
- The Earl of Dundonald, "Improvements in the manufacture of paraffine and hydrocarbon oils." (1864).
- W. Knaggs, "Improvements in the manufacture of sugar, and in the apparatus employed therein." (1867).
- W. E. Gedge, "An improved process for extracting the juice of sugar-cane, beet-root, and other plants." (1867).
- R. S. Lambert, "Certain improvements in the method of and in the apparatus used in the process of combining sulphurous and other gases with mineral bases." (1867).

- W. G. S. Mockford, "Certain improvements in the manufacture of sugar, especially for separating crystals of sugar from molasses and alkaline salts." (1867).
- L. Agostini, "Improvements in the manufacture of sugar." (1867).
- L. Agostini, "An improved method of manufacturing Muscovado sugar in a concrete form." (1867).
- F. Kohn, "Improvements in the mode of extracting the juice from sugar-cane, beet-root, and other plants." (1867).
- R. A. Stewart, "For clarifying and defecating cane juice direct from the mill." (1867).
- W. Garton, "Improvements in the manufacture of inverse sugar, a saccharine material to be employed in brewing and wine-making." (1867).

VICTORIA.

APPLICATIONS FOR PATENTS.

1625. G. A. Lloyd, Sydney, New South Wales, "A new compound to be used as an explosive agent, and called 'Judson's powder.'"—A communication from E. Judson, San Francisco, U.S.A.—Dated April 26, 1872.
1626. J. Watteau, Antwerp, Belgium, "An improved depilatory composition for hides and skins."—Dated May 6, 1872.
- PATENT GRANTED.
1616. F. Sacc, Neuchatel, Switzerland, "Improvements in the preservation of fresh meat and vegetables, and in the preparation of extract of meat."—Dated March 18, 1872.

FOREIGN PATENTS.

FRANCE.

94737. Balpêtré and Donneaud, "Manufacturing liqueur-chocolate."—Dated April 11, 1872.
94754. Guétat, senr., "Reducing and utilising spent baths of chromate, employed in dyeing and printing fabrics."—Dated April 6, 1872.
94787. Herpé, "Obtaining paper and card pulp from the ferula plant."—Dated April 5, 1872.
94792. Morida, "Ventilators and furnaces for burning sea-wreck, and for obtaining charcoal, ashes, and soda, &c."—Dated April 18, 1872.
94796. Sala, "A chemical compound for working quarries and mines."—Dated April 17, 1872.
94804. Anthony, "A vegetable substance for colouring butter."—Dated April 8, 1872.
94808. Bourry, "A chemical process for cleaning wool and woollen fabrics, and also in separating vegetable substances from woollen rags."—Dated April 25, 1872.
94816. Faure and Kessler, "Improvements in concentrating and evaporating various liquids, and especially sulphuric acid at 66°."—Dated April 10, 1872.
94817. Fournier, Pointis, and Durand, "Black of boghead waste."—Dated April 9, 1872.
94824. Lestage, "Decolouring colophony and resinous products."—Dated April 22, 1872.
94830. Piedallu, "A process of tanning hides and means of smoothing and hardening leather."—Dated April 6, 1872.
94834. Young, "Improvements in the manufacture of carbonate of soda and in recovering the substances used therein."—Dated April 6, 1872.
94840. Brin, "A process for preserving food."—Dated April 11, 1872.
94846. Duncan, "Improvements in madder-dyeing."—Dated April 12, 1872.

THE CHEMICAL NEWS.

VOL. XXVI. No. 667.

ON FILIFORM NATIVE SILVER.*

By Dr. J. H. GLADSTONE, F.R.S.

NATIVE silver occurs frequently as metallic threads or wires twisted in every direction, and often bent at sharp angles. Specimens of this filiform silver were exhibited, from Kongsberg, in Norway, associated with calc spar, and from Chili, associated with greenstone, and it was shown that the metal was tough and non-crystalline. Precisely similar threads of silver were produced under the microscope, by decomposing a solution of nitrate of silver with suboxide of copper. The white filaments shoot forth in every direction, and twist about or double back in their course; while the cuprous oxide becomes black, splitting up, in fact, into cupric oxide and cupric nitrate. Most of these threads are so fine that their diameter is only $\frac{1}{1000}$ th of an inch, and a gramme of such silver wire would stretch from London to Brighton, and many are much finer still. Sometimes these filaments will end in crystalline knobs, or crystals of silver will form upon them, as is not unfrequently the case in mineralogical specimens. Attempts to prepare them by means of other substances than suboxide of copper had not proved successful; but, as that substance is by no means a rare mineral, it was thought that their formation might result generally from its action on silver salts in solution.

ON THE MUTUAL HELPFULNESS OF CHEMICAL AFFINITY, HEAT, AND ELECTRICITY, IN PRODUCING THE DECOMPOSITION OF WATER.*

By J. H. GLADSTONE, F.R.S., and ALFRED TRIBE, F.C.S.

SOME metals are able of themselves to displace the hydrogen of pure water, while other metals are unable. Zinc, if perfectly pure, is just incapable of doing so; but, if it be brought into contact with another metal still further removed from the power of effecting the decomposition of water, the electric force started by the contact of the two metals enhances the chemical affinity sufficiently to make it effective; or (otherwise expressed) the chemical force *plus* the electrical increase the tension of water sufficiently to effect its decomposition. The junction of the metals may be made outside the water by a wire; and the amount of action may be determined by a Thomson's galvanometer. The effect of varying the distance of two plates of zinc and copper was tried, and it was found that the chemical action increases slowly till the plates are within about an inch of one another, but on continuing to bring them nearer the action increases at a rapidly accelerating ratio. If the water be heated when it is exposed to this joint action of chemical and electrical force it decomposes more readily. In experiments made with two plates, about 1.5 inches distant from one another, the deflection of the galvanometer showed that the effect of raising the temperature from 40° to 80° C. was more than double of that between 20° C. and 40° C.; but in an experiment made when the copper was deposited in a spongy condition on the zinc,† and the hydrogen gas produced was collected, the following numbers were obtained:—

Mean Temperature.	Duration of Experiment.	Hydrogen collected.	Hydrogen per hour.
22° C.	3 hours	3.4 c.c.	1.1 c.c.
22° " "	2 " "	11.1 " "	5.5 " "
34° " "	45 mins.	10.4 " "	13.9 " "
55° " "	15 " "	15.5 " "	62.0 " "
74° " "	10 " "	29.1 " "	174.6 " "
93° " "	5 " "	44.0 " "	528.0 " "

The last column shows the extraordinary acceleration of the action due to heat.

Magnesium is capable by itself of decomposing water, but its action is greatly increased by touching it with a piece of copper, and some of the hydrogen gas then makes its appearance on the copper plate.

If, instead of magnesium, we take a metal less capable than zinc of decomposing water, we still find a deflection of the galvanometer if it be united with another metal still more negative. The order for pure water seems to be—Platinum, silver, copper, iron, tin, lead, zinc, magnesium.

Experiments were made on the effect of electrical action by using the force generated in one cell of Daniell instead of the force generated by the contact of the metals experimented on. It might be inferred that the electrolysis of water would be more easily effected between the poles made of a metal that has a considerable affinity for oxygen than between poles of a metal which has little affinity. And so it is. When zinc poles were used, there was found to be more than double the action that there was when platinum poles of the same size and at the same distance were employed. The order of efficiency for poles in the electrolysis of water, after about a minute, seems to be—Platinum, tin, silver, copper, iron, lead, zinc, magnesium. After a few minutes the power of tin was found to rise above that of copper. The other metals are in the same order as in the previous list, where they themselves produced the electricity by their joint action on water.

The effect of heat on the electrolysis of water was tried with two zinc poles. The deflection increased about fourfold between 5° and 80° C., and the action increases nearly *pari passu* with the temperature.

If, instead of employing two poles of the same metal, we use dissimilar metals, we have a current established by these two metals, which, according to its direction, either adds to or subtracts from the current originating in the Daniell's cell. Thus, if two poles of platinum be employed, the effect with water is very minute; but if the negative pole be replaced by one of zinc, pure water is decomposed by one cell of Daniell's battery, with visible evolution of hydrogen gas. The experiment was performed quantitatively with poles of silver and zinc.

Positive.	Negative.	Deflection.
Silver	Silver	27
Zinc	Silver	53
Silver	Zinc	7
Zinc	Zinc	33

When, therefore, the dissimilar metals were employed as poles, the decomposition of the water was not the mean of that producible by silver and by zinc, viz., 30, but 30 + 22 when the two forces acted in the same direction, and 30 - 23 when they acted against one another.

THE PRESENCE OF DIDYMIUM IN A SPECIMEN OF PYROMORPHITE.

By CHARLES HORNER.

WHEN recently examining some pyromorphite from Cumberland, I found didymium present in one of the specimens, and, by the intensity of the absorption-lines, should judge the quantity to equal that found in asparagus-stone.

The fact is interesting, since I believe this to be the first published notice of the presence of didymium in an English mineral.

Mortlake, Aug. 24, 1872.

* Read before the British Association, Brighton Meeting, Section B.
† *Proc. Roy. Soc.*, vol. xx., p. 218.

ON THE
EFFECT UPON METEORIC IRON, AS REGARDS
THE CAPABILITY OF BEING FORGED,
OF PREVIOUS HEATING TO REDNESS OR
WHITENESS IN VACUO.*

By J. W. MALLET, Ph.D., M.D.,

Professor of Pure and Applied Chemistry, University of Virginia.

THREE specimens were exhibited of meteoric iron from Augusta County, Virginia. Of these, the first had been cut from the original mass by a planing machine, and, without further preparation, had been forged into a tolerably perfect blade for a paper-knife. The second had been heated to strong redness in a porcelain tube rendered vacuum by a Sprengel pump (for the purpose of examining the occluded gases), and had then been with much difficulty forged into a blade of similar kind, in which cracks and flaws were visible. The third had been heated in like manner *in vacuo*, but to a white heat; and this specimen, it was found, could not be forged at all, crumbling under the hammer when re-heated.

The conceivable causes of these differences were briefly discussed, such as the more or less complete removal of the occluded gases, changed state of combination of the phosphorus (and sulphur), and melting out of phosphide of iron leaving the iron porous.

ESTIMATION OF WORK IN SALINE
SOLUTIONS.

MM. FAVRE and Valson have recently communicated to the Paris Academy an account of some researches by them on this subject, of which we give the following abstract.

When a salt is dissolved in water, there is generally a contraction of the entire volume, which may be easily determined by comparing the density of the solution with the respective densities of the salt and the liquid. But contraction of volume may be produced differently, as by a lowering of temperature, or by mechanical compression. The contractions in these three cases, then, may be considered as effects of the same order, and therefore equivalent with reference to the forces producing them. And as the two last mentioned permit of being measured directly, we may deduce from them a measure of the forces acting in the first. True, the case of the solution is more complex, for, along with contraction of the liquid, there is expansion of the salt, in consequence of the heat yielded by the solvent. But this is so small an element, that, in a first study of the phenomenon it may be neglected.

Suppose, then, a contraction of water through lowering of temperature. Its coefficient of expansion at 15° being about 0.0001320, it follows that, in cooling 1° from this temperature, a litre of water is reduced to 999.8680 c.c., and that a contraction of 1 c.c. per litre is equivalent to a lowering of temperature 7.576°, corresponding to 7576 calories (the grm. being taken as unit). On the other hand, this number measures the work necessary to compress a litre of water and diminish its volume 1 c.c. at 15°.

Suppose, next, a contraction through mechanical compression. The compressibility of water is given by M. Regnault as 0.00004685 per atmosphere; hence, on an increase of pressure 1 atmosphere, a litre will contract 0.04685; and to produce a contraction of 1 c.c., the increase of pressure necessary would be $\frac{1}{0.04685} = 21.34$ atmospheres.

It is supposed that such a compression would disengage 7576 calories, and MM. Favre and Valson propose to submit this point to experimental verification.

Consider, thirdly, the case of a salt dissolved in water.

In order to have a proper idea of this, it may be of use to compare the well-known phenomenon of condensation of certain gases by solid substances, *e.g.* that of carbonic acid by carbon. An equivalent of carbonic acid, passing from the gaseous to the solid state, disengages 3058 calories; whereas in its condensation by carbon it disengages 3278; whence we may infer that the condensation is greater in the latter case. Experiment also shows that the first portions of gas condensed give the greatest liberation of heat, and that this gradually diminishes as the action is continued. Each molecule of the carbon may be considered as a centre round which are grouped successively layers of solidified carbonic acid, which are more and more condensed towards the centre.

The contraction in saline solutions presents comparable results. Suppose, *e.g.*, a crystal of sulphate of soda dissolved in 10 equivalents of water, in which case the anhydrous saline molecule has a coercitive action on the water, producing contraction to the extent of about a 1/10; the aqueous molecules will be condensed about the saline molecules, as the carbonic acid was condensed about the molecule of carbon.

This coercitive action is accompanied by a number of other phenomena, among which may be mentioned, ascent of the boiling- and descent of the freezing-point, and diminution of the tension of vapour emitted by the liquid.

To resume: when a salt is dissolved in water, each saline molecule tends to place itself in equilibrium with the molecules of the surrounding water, the water exercising on the salt a dissociating action, and the salt exercising on the water a coercitive action. This reciprocal influence appears in a sphere of action round each saline molecule, and there results a new equilibrium between this sphere and the rest of the solvent. All the saline molecules act similarly, and the entire equilibrium will be the resultant of the partial equilibria.

If, now, we suppose a quantity of salt, dissolved in a litre of water, to produce a contraction of 1 c.c., comparing this effect with the two previously mentioned, it may be asserted that the forces called into action are equivalent on the one hand to 7576 calories, and on the other to an increase of pressure 21.34 atmospheres. These theoretical results were closely verified by experiment with the anhydrous and hydrated salts of sulphate of sodium.

In such cases of solution the heat liberated by the contraction of the water does not all appear in the calorimeter; it is employed, in part, to melt the solid substance, and becomes latent in this change of state. Another part is employed in the reaction of the dissolved salt in the solvent, and in the special cases just referred to, absorbed by the substance dissolved. This absorption may be observed in cases where the substance dissolved is already in the liquid state, as in the case of a mixture of concentrated sulphuric or acetic acid with water. The quantity of heat liberated is much less than that which corresponds to the contraction of the solvent; whence must be inferred a retention of the difference by the substance dissolved in its reaction with the water.

This presents chemical combinations in a new light. With very rare exceptions, every phenomenon of combination is accompanied with a liberation of sensible heat, but, as has been seen, the number of calories observed does not represent the total heat produced; it is simply the difference between the heat yielded by one of the combining substances (the contracting solvent), and the heat received by the other (the substance dissolved). In most chemical combinations, the passive body receives only part of the heat disengaged, and the rest becomes free as sensible heat. In others, however (as the solution of hydrated sulphate of soda in water, or the formation of explosive compounds, like protoxide of nitrogen), the passive substance requires more heat than the active substance can yield, and then we have production of cold.

It had been remarked in a previous paper, that in various saline solutions, being sufficiently extensive and

* Read before the British Association, Brighton Meeting, Section B.

composed in the same manner (as *e.g.*, 1 equivalent of the salt dissolved in a litre of water), each of the saline radicals increased the density of the solution by a fixed quantity, or *modulus*, which was independent of any other radical associated. Interpreting this result by the foregoing ideas, it appears that each saline radical produces in the solvent a contraction of volume which is proper to it (the radical); now this constant contraction of volume corresponds, in the case of the solvent, to a liberation of heat equally constant; hence in the formation of saline solutions, each saline radical receives from the solvent a quantity of heat which is always the same, and is independent of a second associated radical; this is its *thermal modulus*.

This result finds confirmation in the principle of the *thermoneutrality* of salts, in virtue of which different salts dissolve successively in the same quantity of water act in the same way, from a thermal point of view, as if they were dissolved separately.

Analogous conclusions are arrived at in studying saline solutions from the point of view of capillary action. It has been shown that, for such solutions, there are capillary moduli, as well as moduli of density; and that the product of the density by the capillary height, taken always in a tube of the same diameter, is nearly constant. It follows from the above that there is an intimate relation between these capillary actions and the thermal effects.

A. B. M.

ON THE
METALLURGY OF MANGANESE
AND THE
DOCIMASTIC ASSAYING OF MANGANESE
ORES.

By HUGO TAMM.

THIS paper will raise much criticism; and anything of value which it may contain will be disputed, so that very little credit will be given to me who claims the laying down of the basis of the metallurgy of manganese, which, up to this day did not exist.

The names of Pliny, who described *manganæia* as a black magnesia, of Scheele, who recognised it as a distinct earth, and of Gahn, who isolated manganese, will be thrown at me with alacrity, and I am not quite sure that elaborate articles will not be published establishing as undeniable facts that Tubal Cain knew the use of fire, that lime, fluor-spar, and glass were known of the ancients, and that loam and plumbago are in constant use in the arts. Yet in spite of all this I will feel quite confident that, until now, the metallurgy of manganese did not exist, and that I was the first to establish it on its true basis.

I had a great many practical difficulties to overcome before I was enabled to bring it to the simple form under which I now describe it. I have rendered it almost as simple as the metallurgy of iron; so far, at least, as is consistent with the nature of manganese, a very oxidisable metal. But although I have great faith in the progress of industry, I must confess that I do not think that under present circumstances, and with the common substances at the disposal of chemists and metallurgists, the metallurgy of manganese can be simplified or improved upon.

To do the one or the other new and inexpensive materials which do not exist at present would have to be used, and I repeat that with the actual means at the disposal of industry, the metallurgy of manganese has reached in my hands the last degree of simplicity and perfection which it could attain. However others will judge. The metal obtained by the new process is not pure manganese, it is to manganese that which cast-iron is to iron, and I will henceforth call it cast-manganese. But it is prepared with common materials, and the superiority

of the process consists in this, that with a given manganese ore the cast-manganese is purer than the corresponding metal extracted by another process, and lastly, it is obtained with greater facility, greater security, and at less expense than with ordinary means, and what is most important of all, it may be prepared in unlimited quantity.

If I have been thus successful in creating, so to speak, the metallurgy of manganese, it is because my endeavours were directed from the first to the reduction of manganese ores in presence of a flux. I knew this to be the knot of the question, and I was quite right.

The reason of this will be obvious after I have described the nature of the flux used for the smelting of manganese, and the nature of the slag obtained after smelting.

I will divide this paper into six parts.

- (1). Preparation of the fluxes.
- (2). Preparation of the crucibles.
- (3). Smelting of manganese ores.
- (4). Refining of cast-manganese.
- (5). Properties of cast-manganese, and analyses of the ore and of the metal.
- (6). Docimastic assaying of manganese ores.

Preparation of the Fluxes.—Two fluxes are required for successful and really practical operations in the smelting of manganese. One which I will call flux No. 1. of white flux, and which is obtained by mixing well together common ground bottle glass free from lead, quick-lime, and fluor-spar. The following are the exact proportions to be mixed.

Ground glass	63 parts
Quick-lime	18½ "
Fluor-spar	18½ "

100

This flux is the original flux from which the others are made, but it is used also *per se* to add to the fusibility of the others.

The second flux, flux No. 2., or black flux, is theoretically required for the smelting of manganese, and it can be used in practice. It is formed by mixing:—

Flux No. 1. (white flux)	6½ parts
Native oxide of manganese, of good quality ..	35 "
Very fine charcoal powder, soot, or lamp-black	3½ "

100

This flux may be used just as it is obtained after mixing. But it is best to incorporate the mass by adding enough of an oil to form a thick paste, and heating the whole at a high temperature in a closed crucible. The oxide of manganese is reduced to the state of protoxide, the flux assumes a fine olive green colour. It may be ground and kept for any docimastic or metallurgical operation on manganese.

But on the whole, the best and safest mode of operating is the following. A mixture is made of:—

Flux No. 1.	34 parts
Lamp-black, or soot of good quality	5½ "
Peroxide of manganese, native, of good quality	60½

100

And it is smelted as will be hereafter described. 17½ parts of cast-manganese are obtained, and the slag which presents a fine olive green colour, is ground. It is saturated with protoxide of manganese, to which it owes its colour, and it forms an admirable flux, either for the smelting of manganese ores or for their docimastic assaying. I shall henceforth always design the flux thus prepared as flux No. 3, or green flux.

I have not made a full analysis of this flux, which might be interesting in some respects, for the reason that I expected no practical result from such an analysis, or, indeed, no theoretical considerations of real value. The

flux contains of course all the elements of flux No. 1, *plus* a large amount of protoxide of manganese, *plus* a certain quantity of the oxide of iron and the silica and earthy matters contained in the manganese ore, and we will see, by-and-bye, how this slag, for it is nothing else but a slag, has acted during the smelting. When this flux is prepared specially for docimastic purposes, it ought to be made with the native oxide of manganese. When once the green flux has been obtained, the extraction of manganese presents no further difficulty, because it can be used over and over again providing the oxide of manganese reduced is of a tolerably good quality, and introduces no injurious material in its slag. This slag being saturated with protoxide of manganese, is as good as the original flux, and the only improvement which it requires, is the addition from time to time of a little white flux, to add to its fusibility, which might be slightly impaired by the incorporation after each smelting of the gangue of the ore.

Green flux is formed of three distinct parts; glass or dissolving agent, to which lime may be added; fluor-spar, or fluidifying agent; and protoxide of manganese and lime also, or refining agents.

I will not dwell at length on its chemical properties, but I will resume them in a few words.

(1). It becomes very fluid at a high temperature, and allows the metallic grains to collect easily in a mass.

(2). Its silicates, besides dissolving the earthy matters of the gangues, add some silicium to cast-manganese, and add to the fusibility of this metal.

(3). The silicates form with protoxide of iron a silicate irreducible by carbon.

(4). The protoxide of manganese with which it is saturated acts as a refining agent, and it prevents cast-manganese from absorbing more than a certain proportion of silicium, of carbon, of iron, or of earthy metals.

(5). Its chief property is that it does not dissolve oxide of manganese, and that it allows the whole of the oxide mixed with it to be reduced to the metallic state.

These few facts of importance once established and understood, we will proceed.

Preparation of the Crucibles.—My successful efforts in discovering a perfect flux for the reduction of manganese would have been unavailable had I not succeeded in overcoming another apparently insuperable difficulty. At the high temperature required for the smelting of manganese, no crucibles could stand the flux, and they were all destroyed. I tried pots of every description, even the best plumbago crucibles, but none would stand the molten flux.

I could not think of using pots lined with charcoal in the usual fashion, because this kind of lining is not practicable on a large scale, but the following plan which I devised is so simple and so effective that not only is every difficulty removed, but special advantages are attached to its use.

Three parts of plumbago, and 1 part of loam or fire-clay are mixed together, and made into a thick paste with water, and the crucible is as equally as possible lined with this paste, which holds firmly to its sides. The thickness of the lining varies with the size of the crucible, but with the largest crucibles it should not exceed half an inch.

The properties of this lining are worth mentioning.

(1). It stands the destroying effect of the flux to perfection.

(2). A crucible so lined may be used immediately after it is lined, providing it is gradually heated.

(3). After smelting, neither flux nor metal adhere to the lining, and both may be extracted quite easily by reversing the crucible and tapping it gently.

This last fact is very important, since both the crucible and its lining can be used several times. Still after each smelting the lining wants repairing slightly with the mixture of loam and plumbago, made into a somewhat thinner paste than at first, and the outside of the crucible must be repaired with a little thin fire-clay.

I think it is just as well to give these apparently tedious details, which have their importance; but should I omit anything, with a little practice the best modes of working would soon be found out. The discovery of a flux, in presence of which manganese could be reduced, and of a crucible which could stand the destroying action of the flux, were the two real difficulties to be overcome; the remainder presents no real difficulty.

Smelting of Manganese Ores.—The proportions which will be given are those which were found to succeed best with a manganese ore of good quality, and they do not admit of much alteration; but still the general process is of course open to slight modification, according to circumstances and to the nature of the ore used.

Any crucible which will stand a white heat for several hours without softening can be used. It is lined with loam and plumbago, as I have previously described, and then the following mixture is introduced into it:—

Native oxide of manganese of good quality	1000 parts.
Lamp-black or soot of good quality	91 "
Green flux	635 "
Oil, in sufficient quantity to merely wet the mixture.	

Any kind of oil is good enough for the purpose. The mixture must be made shortly before introducing into the crucible; for if it is left standing for some hours, especially in an open vessel, it is apt to catch fire, and is then unfitted for smelting. Should this occur, the addition to the burnt mixture of about 45 parts of lamp-black or soot and some more oil would remedy the accident. But it is only after standing for some eight hours that the mixture takes fire.

The mixture is introduced in the crucible and slightly pressed in, and a round cover of thick wood is placed over it. It is carbonised during the smelting, and forms a charcoal cover which protects admirably the mixture from oxidation, and it can be used several times.

The clay or plumbago cover is then placed over the crucible, and the joint is luted with a little thin fire-clay. A small aperture is kept to allow the gases to escape.

The crucible is then placed in a wind- or blast-furnace, and slowly heated so long as fumes escape from the crucible. The heat is then rapidly increased until it reaches white heat, and the furnace is maintained at that high temperature for several hours, the time required depending, of course, on the quantities operated upon.

When it is thought that the operation is done, the fire is allowed to burn away and the crucible is left to cool. The cover is then removed by means of a chisel introduced in the joint. The crucible is turned upside down, and shaken until the slag and metal fall down. The button of metal is detached from its slag with a hammer, and introduced in well-corked or stoppered vessels perfectly dried.

The slag, which has a fine olive-green colour, breaks up in fragments with large faces affecting a pseudo-crystalline structure, but the grain is really crystalline. It is ground, and used as flux in a second smelting. It is advisable after each smelting to add to the slag, in order to make it more fusible, about 1-10th of the white flux.

The mixing of manganese ore, lamp-black, and flux is not an indifferent operation, and to ensure perfect success it should be done in the following way:—The oxide of manganese should be first of all thoroughly mixed with the lamp-black. Then this mixture should be pretty roughly mixed with the flux, and then oil should be added. By so doing, lamp-black and oxide of manganese remain united during the mixing, and act upon each other during the smelting, before the flux begins to melt, so that the oxide is reduced to the metallic state before the flux can dissolve any portion of it. The residue of carbon left by the burnt oil assists in reducing the oxide of manganese, and in preventing the flux from acting upon it before it has been reduced to the metallic state.

It is almost an extraordinary thing that, according to the

manner in which substances have been mixed, their chemical reactions should differ; but it must be borne in mind that, in docimastic or metallurgical operations, several successive chemical reactions take place at intervals. Hence the real importance of a systematic way of mixing.

If manganese ores of very bad quality were to be used, the slag would of course, after a few operations, become unfitted for further use; but, with good manganese ore, the slag can be used over and over again, and forms an admirable manganese flux.

Very little need be added to these general considerations: the general process will undoubtedly undergo some slight alterations at the hands of those who may be tempted to use it; but the main facts established here must perform remain the same, the more so that I have been unsuccessful in modifying them deeply. It is extremely doubtful whether any improvements will be made upon the process, chiefly because such improvements could scarcely add to the simplicity of the operation. The only real improvement of importance would be the addition to the flux of a substance which, in small quantities, would assist in obtaining a cast-manganese of a superior quality.

It is worthy of remark that, in presence of either the white or the green flux, charcoal, even in very fine powder, cannot be substituted for lamp-black or for soot. Charcoal-powder does not reduce the oxide of manganese to the metallic state, but only to that of protoxide. On the contrary, with the proportions previously given, lamp-black reduces 420 parts of manganese from 1000 parts of peroxide, or nearly the whole of the metal which it contains.

Is this difference due to the physical condition of both forms of carbon, or to their chemical constitution? Does the non-volatile carburet of hydrogen contained in soot or lamp-black exert a more powerful reducing action than carbon itself? This is very possible, but I have not studied closely this question and am not prepared to answer it.

Refining of Cast-Manganese.—There is little doubt that, as soon as manganese is prepared on the large scale and at a comparatively low price, some uses will be found for it. I think that, in certain operations, it might form a good substitute for potassium and sodium; and in that case cast-manganese, such as is obtained after the smelting of its ore, could be used with advantage; but, should a purer kind of metal be required for the manufacture of certain special alloys, cast-manganese would have to be refined.

The simplest way of refining manganese is the method which has been proposed by Berthier I believe, and which consists in re-melting the cast-manganese coarsely powdered with about one-eighth of carbonate of manganese. The mixture is introduced into a refractory clay crucible, and covered over with a wooden cover similar to the one used in the smelting, to prevent oxidation.

I need not make any further remarks on so simple an operation.

Properties of Cast-Manganese: Analyses of this Metal and of the Ore.—The properties of cast-manganese, of the refined metal, and of pure manganese are those which are so well known, which have been described so often, and which may be found in any treatise on chemistry. The handling of unlimited quantities of cast-manganese did not bring out any new or remarkable properties worth mentioning. The ore operated upon during the course of these investigations presented the following composition:—

Peroxide of manganese	79.50
Peroxide of iron	6.50
Water	3.50
Phosphate of lime	trace
Gangue	10.50

100.00

It contains, consequently, 50.5 per cent of metallic manganese and 6.5 per cent of metallic iron.

The cast-manganese obtained from this ore presented the following composition:—

Manganese	96.90
Iron	1.05
Aluminium	0.10
Calcium	0.05
Phosphorus	0.05
Sulphur	0.05
Silicium	0.85
Carbon	0.95

100.00

100 parts of the ore, containing 50 per cent of manganese, yielded from 42 to 45 per cent of cast-manganese, containing only 1 per cent of iron, while the ore itself contains 6.5 per cent of this metal.

Cast-manganese, refined by carbonate of manganese, presented the following composition:—

Manganese	99.910
Iron	0.050
Silicium	0.015
Carbon	0.025
Other substances	traces

100.000

Docimastic Assaying of Manganese Ores.—Should works be erected for the extraction of manganese on the large scale, the docimastic assaying of manganese ores would undoubtedly offer great interest and be of great consequence. In the course of two hours at most several assays might be made, giving an accurate estimation of the amount of metal which a given ore would produce on the large scale, and enable the metallurgist to judge of the quality of the metal obtained.

The docimastic assaying of manganese ore is performed exactly as the corresponding mode of valuation of iron ores, with, however, the modifications required by the new metallurgy. Some white flux and some green flux, prepared exactly as I have described in the metallurgy of manganese, should be kept at hand with the other requisites of the metallurgy of manganese, carbonate of manganese, lamp-black, oil, and a mixture of loam and plumbago.

The experiments should be made on quantities varying from 500 to 1000 grs. of the ore, and the whole of the operations should be carried out on the small scale exactly as I have described them on the large scale, without any other modification than that of the reduction of the proportions.

I trust that my labours will be lost to neither science or industry, but that they will be the means of opening a new field of research to the one and of useful appliances to the other.

ON A SIMPLE APPARATUS FOR THE PRODUCTION OF OZONE WITH ELECTRICITY OF HIGH TENSION.

By Professor ARTHUR W. WRIGHT.

EXPERIMENT has shown that, in the production of ozone by electricity, the maximum amount of oxygen is ozonised by the silent or glow discharge, and most of the forms of apparatus by which this is effected are contrivances by which oxygen is made to flow slowly through a space traversed by such a discharge. In Von Babo's apparatus, as well as in those of Siemens and Houzeau, the metallic conductors are separated by glass and a stratum of air. By inductive action of the charged metallic surfaces the intervening air becomes charged with electricity oppositely

upon its two sides, and simultaneously with the discharge of the metallic terminals, through the wire of the coil, a discharge takes place through the air, not in the form of sparks, but diffusely, producing a glow of purplish light visible only in the dark.

These apparatus succeed best with electricity of comparatively low tension. In using the Holtz's electro-machine with them the discharge is apt to occur chiefly in the form of sparks through the air, or it may even traverse and perforate the glass, and the form of the apparatus must be varied to give the best results.

When the poles of the machine itself are separated to a sufficient distance, the electricity passes between them, either in the form of a diffuse brush, spanning the whole interval, or with a very minute brush upon the negative pole, and a glow upon the positive, the intermediate space not being visibly luminous. This is the so-called dark, or silent discharge, exhibiting the phenomena of the electric shadow when suitable objects are interposed, as described in a former paper.* When this occurs, the strong odour shows that a considerable amount of the atmospheric oxygen is converted into ozone.

If this discharge is made to take place in an enclosed space through which air or oxygen can be driven, the ozonising effect of the electricity is heightened and can be utilised. The apparatus which I have employed, and which has afforded very satisfactory results, consists of a straight glass tube about 20 centimetres long and having an internal diameter of 2½ centimetres, the two ends being stopped with corks covered on the inner side with a thin coating of cement to protect them from the action of the ozone. Through the axis of each cork is inserted a glass tube of about 5 m.m. calibre and 7 centimetres in length, having a branch tube inserted perpendicularly at the middle and long enough to permit a rubber tube to be slipped upon it. The outer ends of the tubes themselves are closely stopped with corks, through which are passed straight, thick copper wires carrying suitable terminals at their inner ends, and bent into a ring at the others. They are fitted so as to make tight joints, but to allow of motion in order to vary the distance between their inner ends. One of these wires carries a small ball; the other terminates in a disc with rounded edge, set perpendicularly to the axis of the tube, and so large as to leave an annular space of some 2 or 3 millimetres breadth around it. The gas is admitted through one of the branch tubes and escapes from the other, after having passed through the whole length of the tube.

In using the apparatus, the wires must be connected with the poles of the machine in such a manner that the disc becomes the negative terminal, as this arrangement gives the greatest degree of expansion and diffuseness to the current. On turning the machine and adjusting the ball and disc to a proper distance, a nebulous aigrette surrounds the latter, quite filling the interval between it and the wall of the tube, while the part of the tube between the disc and ball is crowded with innumerable hazy streams converging upon the positive pole, or simply causing the latter to be covered with a faint glow. A current of air or oxygen sent into the tube must pass through this, and ozone is very rapidly produced, and in great quantity. The condensers are of course not used with the machine when this apparatus is employed.

There appears to be an advantage in causing the oxygen to pass from the negative toward the positive within the tube, for the gas through which the discharge passes is transported in the contrary direction, as may be readily seen on bringing a candle-flame between the poles of the machine, or causing a thin column of smoke to rise through the polar interval. The flame and the smoke are deflected, and stream off toward the negative pole. If the gas should be admitted in the direction mentioned, there would be a tendency to obstruct its flow somewhat, and thus keep it longer under the influence of the electricity.

Some experiments which were made with the apparatus

will give an idea of its efficiency. 100 c.c. of water were placed in an upright tube or test-glass, and into it were put 20 drops of strong indigo solution, causing it to assume a deep blue tint. Air was driven through the ozonising tube, under a pressure of about 3 inches of water, and on issuing from it conveyed by a tube into the solution. When the electro-machine was put in operation, being turned with sufficient speed to give nearly its maximum effect, the solution completely lost its blue colour in less than four minutes. Blue litmus solution under similar circumstances became pale pink, but required a considerably longer time for the change.

When Schönbein's test solution is employed the deep blue colour is immediately produced, but the solution is too thick to work well if the starch has been heated considerably, or for a long time, in making it. A better proportion is to take 1 part of potassic iodide, by weight, 10 parts of starch, and 5000 parts of water. This forms a milky solution, sufficiently mobile to mix well when the ozonised air bubbles through it. When 100 c.c. of this solution were used, and air passed through the apparatus as before, the blue colour appeared at once on application of electricity, and in thirty seconds it was deeply coloured.

With dry oxygen the effects were much more rapid and remarkable. 100 c.c. of the solution were used, as before. The instant the machine was put in action the liquid about the end of the delivery-tube became deep blue, and in from ten to fifteen seconds the whole had acquired a uniform and intense blue colour.

The summer moisture having interfered somewhat with the effective working of the electro-machine, there has been no opportunity to determine the percentage of ozone produced in this manner, but it appears to be very large. When dry oxygen is passed through the tube very slowly, the issuing gas, when inhaled, produces a painful burning sensation in the lungs, and causes violent coughing, which persists for a considerable time.

When oxygen is used, it is found that the electrodes must be separated to a much greater distance than is necessary for air, otherwise sparks pass and destroy a large proportion of the ozone already formed. With air, the direct spark in the apparatus could not be made to pass over an interval of more than 7 centimetres, but in oxygen they did not cease until the poles were separated about 11½ centimetres. When the tube was filled with air, and the poles were 7 or 8 centimetres apart, the discharge was of the silent kind, but on admitting oxygen it immediately took the form of direct sparks.

The quantity of the solution used in these experiments was much greater than would be needed in order to exhibit the characteristic reactions of ozone to an audience of moderate size. One-half or one-third of the amount would be quite sufficient, and the time required for the reaction would be proportionally shorter. The great quantity of the ozone, as well as the ease and rapidity with which it is produced, render the apparatus especially serviceable for use in the lecture-room.—*American Journal of Science.*

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.*

By Dr. F. CRACE CALVERT, F.R.S.

(Continued from p. 92).

Orchil, Cudbear, Litmus.—I shall now call your attention to a colour which was discovered in 1300, by an Italian named Federigo, who, during his travels in the East, observed the tinctorial powers of a certain class of weeds called *lichens*, and he introduced the colour into Florence under the name of *orchil*. By this discovery he and his family made a very large fortune.

* The Cantor Lectures, delivered before the Society of Arts. Revised and communicated by the Author.

* *Am. Journ. Sci.*, II., vol. xlix., p. 381, and III., vol. i., p. 437.

Lichens are small plants which live either in the stems or leaves of trees, or on rocks, or damp soils. To this class belongs all the vegetation found in the Arctic circle, but the species growing there are not employed to produce the colouring matter orchil, the varieties used for this purpose being found in warmer, and especially in tropical climates. These latter can be divided into two classes; the first and most abundant, which grow on rocks near the seaside, includes the species *Roccella tinctoria* and *Roccella fuciformis*. They are obtained from the Canary Islands, Cape Vere, and Sardinia, but principally from Madagascar, Zanzibar, Angola, and South America. The second class grows inland, and includes the species *Variolaria orcina*, found especially in the Pyrenées.

Lichens do not contain any colouring matter already formed, but contain colourless acids, which, under the influence of ammonia and the oxygen of the atmosphere, give rise to the orchil. As the lichens imported into this country vary considerably in the amount of orchil which they yield, Dr. Stenhouse has rendered a great service to the manufacturers in furnishing them with a simple and accurate process of ascertaining their commercial value. The following is an outline of his method:—100 grs. of the lichen are macerated with a dilute solution of caustic soda, two treatments being sufficient to extract the whole of the colouring matter. A solution of hypochlorite of sodium of known strength is added to the soda solution from a graduated alkalimeter; the moment the bleaching-liquor comes in contact with the soda solution of the lichen a blood-red colour is produced, which disappears in a minute or two, and the liquid has only a deep yellow colour. A new quantity of bleaching-liquid should then be poured into the soda solution, and the mixture carefully stirred. The operation should be repeated as long as the addition of the hypochlorite of sodium causes the production of the red colour, for this shows that the soda solution still contains unoxidised colouring principle. Towards the end of the process the bleaching-solution should be added by only a few drops at a time, the mixture being carefully stirred between each addition. By noting how many measures of the bleaching liquor have been required to destroy the colouring matter in solution, the amount of colouring principle contained in the lichen may be determined.

The manufacturers of orchil are also indebted to Dr. Stenhouse for a process of obtaining the orchil, which, besides simplifying the operations required, gives brighter colours and extracts than could be produced before the publication of his method, in 1848. Of this you will easily judge when I tell you that the process carried on for centuries consisted in breaking up the weeds in water, to which putrid urine, lime, and carbonate of soda were added from time to time. After two or three months exposure to the air, the colourless principles of the lichen became transformed into the colouring matter orchil. As the science of chemistry progressed, and cheap means of producing ammonia were devised, this compound was substituted for the urine. Dr. Stenhouse's process consists in exhausting the lichens, by macerating them with milk of lime, squeezing the liquor off, and after having repeated this treatment two or three times, he adds an acid to the liquors, when a white gelatinous precipitate is produced, which, when collected and placed in contact with ammonia, gives rise to orchil.

You are doubtless aware that the beautiful purple and mauve colours obtained on silk and wool from orchil are extremely fugitive, losing their brilliancy on exposure to the light or to the influence of weak acids, such as sulphurous, which is abundantly produced in our manufacturing districts. M. Marnas, of Lyons, succeeded in the year 1856 in making orchil colours which gave fast purples and mauves.

Before describing this valuable discovery, allow me to state that it had a most important bearing on the marked progress which the art of calico-printing has made since

the date above mentioned. Until that time, neither dyers nor calico-printers would use expensive dyes, but since then, they have paid as much as £40 or £50 per pound for the solid dye-stuff, although these enormous prices have been apparently decreased by the colours being sold in the state of paste or solution.

The demand for a fast purple in this country was so great, consequent on the introduction of the fast purples and mauves on the Continent by M. Marnas, that attention was directed to the preparation of these colours. Mr. Perkin had obtained from aniline a fine purple colour, as fast as the orchil colours, and M. Béchamp discovering about this time a method of producing aniline artificially from benzine, Mr. Perkin was enabled to manufacture his colour commercially. This may be considered as the first successful step towards the introduction of the splendid and varied coal-tar colours which are now so universally admired.

Returning from this digression, let us now enter on a description of the process of M. Marnas. He treated the lichens, as suggested by Dr. Stenhouse, with milk of lime, filtered the lime liquor off, precipitated the colour-giving principle from it with hydrochloric acid, and gathered the precipitate on a filter. This precipitate was well washed, dissolved in caustic ammonia, and the ammoniacal liquor kept at a temperature of 153° to 160° for twenty to twenty-five days, when, under the influence of that temperature, the colour-giving principles of the lichens fix ammonia and oxygen, and are transformed into a new series of products. These were separated from the liquid by the addition of chloride of calcium, which caused a fine purple-lake to be deposited. This, after being washed and dried, was sold under the name of French purple.

To dye silk or wool with French purple, it is simply necessary to mix the lake with its weight of oxalic acid, boil with water, and then filter, the oxalate of lime remaining on the filter, while the colour passes through in the filtrate. This liquor is added to a slightly ammoniacal liquid in the dye-beck; all that is now necessary is to dip the silk or wool in the beck, when they will become dyed with magnificent purple or mauve.

To dye cotton, it is necessary to mordant it with albumen, or prepare it as for Turkey red, before putting it in the bath.

Robiquet was the first chemist to isolate a colourless principle from lichens susceptible of assuming a fine purple hue when brought in contact with ammonia and oxygen. This principle he named *orcine*. He obtained it by treating the *Variolaria orcina* by strong alcohol. This solution, on being allowed to cool, gives crystals, which, on being dissolved in water and allowed to crystallise, assume the form of large well-defined crystals of hydrate of orcine. By crystallisation from ether, anhydrous orcine can be obtained. Orcine gives a fine, dark red colour with perchloride of iron; but its most remarkable property is its transformation into *orcéine*, which Robiquet shows to be due to the following reaction:—

Orcéine presents itself under the form of a brown powder, slightly soluble in cold water, to which it gives a red colour. It is soluble in alcohol, but insoluble in ether. It is soluble in alkalies and ammonia, to which it communicates a magnificent violet colour. It exists in commercial orchil under the form of orcéinate of ammonia.

Time will not permit me to describe the researches of Heeran and Sir R. Kane. I must therefore confine myself principally to a short description of those of Dr. Stenhouse and Dr. Schunck.

The chief merit of Dr. Schunck consists in having pointed out the connection which exists between the orcine of Robiquet, and the *erythrine* and *pseudo-*

erythrine of Heeran, and in showing that orcine is the sole immediate colour-producing principle of the series. This he proved by his researches published in 1842, in which he treated the dried and powdered *Variolaria orcina* by ether. On evaporating this solution, there remained a residue, from which he isolated a substance which he called *lecanorine* or *lecanoric acid*. This compound crystallises in white needles, and gives a red colour with bleaching-powder, and a dark purple with perchloride of iron. It yields a similar colour when dissolved in ammonia and exposed to the atmosphere. Its most interesting property is its conversion into orcine and carbonic acid, when boiled with an aqueous solution of baryta. The reaction is:—

He found also that on boiling lecanorine with alcohol it formed an ether, which proved to be identical with the pseudoerythrine of Heeran.

Dr. Stenhouse has succeeded in extracting the important compounds to which he has given the names of *erythrite* and *orsellic acids*. The first mentioned body is a product of the decomposition of erythrine under the influence of lime-water. The erythrine splits up into carbonic acid, orcine, and erythrite, according to the following equation:—

The orsellic acids were obtained, one from the South American weed, the other from the South African. The first appears to be identical in composition with lecanorine, and is capable of splitting up under the influence of baryta or lime into carbonic acid and orcine. The one from the latter appears to be composed of lecanoric acid and a substance called roccellinine. According to Schutzenberger, lecanoric acid may be made to undergo a decomposition into orsellic acid, or may be further converted into orcine.

The employment of orchil is at the present day comparatively limited, but it is still used for producing browns, maroons, and other dark shades, in conjunction with other dye-stuffs. Its chief use is to top cheap indigo blues on woollen goods; this is effected by lightly dyeing the fabric with indigo (an expensive dye), and then passing it through a bath of orchil, which gives to the cloth a rich purple hue, similar in appearance to one dyed wholly with indigo.

Cudbear is a special preparation of orchil, first manufactured by Dr. Cuthbert Gordon, from whom it derives its name.

Litmus is obtained from the same lichens as those employed for producing orchil, only lime and carbonate of potash are added to the ground weed and urine; in fact, the process is very similar to that used in former times to produce orchil. After three or four weeks, a blue colour is fully developed, when it is mixed with sulphate of lime or chalk, dried, and is ready for market. The chief employment of litmus is to communicate a peculiar tint to the cheese made in Holland.

Prussian Blue.—I shall now have the pleasure of drawing your attention to one of the finest, brightest, and most permanent colours known. It was discovered accidentally in 1710, by a colour manufacturer named Diesbach, of Berlin, from which it derived its name. The process by which it was produced was kept a comparative secret until 1724, when Dr. Woodward showed how the colour had become a very profitable affair, and described a process by which it could be obtained. The process has in time undergone many improvements; but I shall here confine myself to a description of it as now carried out. I shall be obliged here to enter slightly into theoretical chemistry.

Prussian blue is a combination of iron with cyanogen, a compound of carbon and nitrogen. There are two well defined cyanides of iron corresponding to the two oxides,

the *protocyanide*, Fe.Cy. and the *sesquicyanide*, Fe₂.Cy₃. These two cyanides combining together in different proportions give rise to the various shades of Prussian blue found in commerce. But, strange to say, you cannot produce either of these compounds or Prussian blue by the direct combination of cyanogen with iron. Cyanogen must be first united with potassium, giving rise to cyanide of potassium, under the influence of which salt the iron combines with cyanogen, and the cyanide of iron thus formed in its turn combines with the cyanide of potassium, forming a double cyanide. There are two double cyanides of potassium and iron; the first, called ferro-cyanide of potassium, or yellow prussiate of potash; the second, ferricyanide, or red prussiate of potash. The formulæ may be represented as follows:—

Yellow prussiate .. Fe.Cy.+KCy.

Red Prussiate Fe₂.Cy₃+3KCy.

To produce Prussian blue from these salts, it is necessary to replace the potassium by iron. This is effected by adding a persalt of iron to the yellow prussiate or to the red prussiate, a proto-salt of iron. The iron of the iron salt replaces the potassium of the double salts, and double cyanides of iron are produced, as seen by the following formulæ:—

That this is the case can be easily demonstrated, for if you mix together a solution of persalt of iron and one of red prussiate, which contains only percyanide of iron, no Prussian blue is formed. Again, if you mix yellow prussiate of potash with protochloride of iron, you get no Prussian Blue, because, in the first case, you have no protocyanide of iron present, and, in the second, you have no percyanide.

Simple as the production of Prussian blue appears, it requires much practice to prepare it with certainty as a pigment where a given shade of blue is required. It is seldom found pure in commerce, being generally mixed with starch, chalk, or gypsum. Sometimes they are added with a view to deception, sometimes in order to produce a lighter shade of colour. The testing of a Prussian blue by chemical means is not, therefore, a true criterion of its quality. The method usually employed consists in grinding in oil equal weights of a Prussian blue of known value, and of the one to be tested, white-lead is added to each, and the intensity of the colours compared.

The best quality of Prussian blue is obtained by mixing a dilute solution of red prussiate of potash with proto-salt of iron; the second quality is made by mixing yellow prussiate of potash with permittate of iron, and is called *Turnbull's blue*. Cheaper qualities are made by mixing solutions of yellow prussiate and protosulphate of iron (green copperas), which produces a pale blue precipitate. This is transformed into Prussian blue by the addition of bleaching-powder, which oxidises part of the iron, and transforms the protocyanide into percyanide. For still lower qualities, alum is mixed with the iron solution previously to the prussiate being added. Alumina is by this means mixed with the blue.

Prussian blue was first obtained on silk fabrics in 1811, by a professor of chemistry at Lyons, named Raymond, in consequence of the high premium offered by the First Napoleon for the production of a fast blue, as indigo could not at that time be imported into France. His process, with slight modifications, is followed at the present day, although the colour is not much used, owing to the introduction of the aniline blues. It consists in dip-

ping the silk, for several hours, in a salt of peroxide of iron, when the oxide of iron becomes fixed in the silk, which is washed and dipped in a slightly acid solution of yellow prussiate of potash. Prussian blue is thus produced on the silk, which only requires washing to be ready for market. The only improvement made in this class of dyeing has been the addition of a persalt of tin to the iron-salt.

The production of Prussian blue on cotton or woollen fibres is effected by a curious chemical reaction. At a temperature of 212° F., all acids, even the organic, such as oxalic, citric, and tartaric, as well as the acid sulphates, possess the property of decomposing the two prussiates. The potassium of the cyanide combines with oxygen of the water, and with the organic acid. The cyanogen thus liberated unites with the hydrogen of the water, forming prussic acid. The cyanide of iron liberated unites with the fibre of the cloth, and on the latter being passed into a weak solution of bichromate of potash or bleaching-powder, or if it is left exposed to the air, part of the protocyanide of iron is converted into sesquicyanide, and Prussian blue is produced. As salts of tin greatly facilitate the fixing of the prussiate on the cloth, chloride of tin is now generally mixed with the prussiate of potash. In this case prussiate of tin is produced. To this mixture tartaric or oxalic acid is added; it is then properly thickened and printed on the calico. When the design is dry, the fabric is submitted to the action of steam, and the blue is produced on the fabric. It then only requires to be passed through a bath of bichromate of potash to develop the full depth of the shade.

Ultramarine Blue is a most valuable pigment, both on account of its cheapness and the brilliancy of its colour. It is used extensively in many branches of trade—by the calico printer in pigment printing, by the paper stainer and manufacturer, the typographic and lithographic printer, by the match manufacturer, the sugar refiner, and by the house decorator. The value of the pigment depends on the fineness of the powder, and the brilliancy of its hue.

The greatest care and much experience are required in every stage of the manufacture, in purifying the substances employed, in mixing, in heating at the proper temperature, and in grinding, washing, and drying the manufactured mass. Fourteen distinct operations are required to produce it, and it would take too much time at this late hour to enter into the details of these processes. I will therefore only attempt to give you a very rough outline of the principal points of the manufacture.

The proportion of materials used may be as follows:—

White china clay, or kaolin	50 parts
Sulphate of soda	19 "
Sulphur	25 "
Charcoal	12 "
Carbonate of soda	28 "

134

These substances are most intimately mixed together, and introduced into an earthenware crucible, which is carefully closed and heated at a temperature of about 500° F. for 12 hours. The temperature is then gradually raised till it reaches a white heat at the end of 48 hours; the fire is then removed, and the crucible allowed to cool gradually in the furnace. The mass, as taken out of the crucible, is of a beautiful bright green colour. It is ground, washed and dried, and then calcined in an open furnace, to oxidise it; but as the slightest excess of oxidation spoils the colour, the workman from time to time adds a small amount of sulphur to the mass, by this means controlling the oxidation. The green mass gradually becomes blue, and is washed and dried, when it is ready for market.

The colouring-matter of ultramarine is not well known. It is supposed to be a peculiar sulphite or hyposulphite of soda. The solid matter itself is a double silicate of

soda and alumina. What is certainly worth notice is that, although we are ignorant of the true colouring matter of this pigment, we find its composition to be almost identical with that of the natural *Lapis lazuli*, which, although very costly, was employed by printers for many centuries. The following analyses will show the similarity of composition:—

	Lapis lazuli.	Ultramarine.
Silica	45'40	46'60
Alumina	31'67	23'30
Soda	9'09	21'46
Potash	nil	1'75
Iron	0'52	1'06
Lime	3'52	0'02
Sulphuric acid	5'89	3'08
Sulphur	0'95	1'68
Chlorine	0'42	trace
Water	0'12	nil
Loss	2'42	1'05
	100'00	100'00

Artificial ultramarine was discovered by a French chemist and druggist, named Guimet, who kept the process of its manufacture secret for many years.

(To be continued).

CORRESPONDENCE.

DECOMPOSITION OF SULPHURIC ACID BY HYDROGEN.

To the Editor of the Chemical News.

SIR,—In discussing a paper I read before the Chemical Section of the British Association, I incidentally mentioned that in a battery with dilute sulphuric acid for the electrolyte, zinc for positive, and carbon packed in granulated carbon for negative, I found a coalition of sulphuretted hydrogen from the carbon, which could only be produced by the partial decomposition of the sulphuric acid.

The possibility of this was strongly doubted by several members of the Section, who attributed it to the contamination of the carbon by a sulphide of iron. On the spur of the moment I forgot to reply to this, that the sulphuretted hydrogen was only evolved when the battery was in action. It is plain that if it arose from impurities in the carbon, it should equally be evolved when the battery was at rest.—I am, &c.,

H. HIGHTON.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, August 26, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

Action which Charcoal and Iron Exert at Red Heat upon Carbonic Acid Gas.—Dr. J. Dumas.—In this exhaustive memoir the eminent savant communicates the results of a series of experiments made by him, from which the following conclusions may be drawn:—When absolutely dry carbonic acid gas is passed over charcoal entirely freed from hydrogen, and heated to cherry-red heat, the gas is con-

verted into oxide of carbon; when there is an excess of charcoal, the whole of the carbonic acid gas is converted into oxide of carbon. The charcoal, even when strongly ignited in closed vessels energetically retains hydrogen or water, which cannot be eliminated except by exposing the charcoal for a long time to a current of chlorine gas at red heat; charcoal not so treated yields, when employed for the conversion of carbonic acid into carbonic oxide, a gas contaminated with traces of hydrogen. When a slow current of dry carbonic acid gas is passed over iron at bright red heat, a portion of the carbonic acid is converted into oxide of carbon; the bulk of the carbonic acid, however, is left unaltered.

New Propionic Studies.—I. Pierre and E. Puchot.—The authors have prepared perfectly pure propionic acid at its highest degree of concentration; its formula is then $C_3H_5O_2$, HO; boiling-point, 146.6° ; sp. gr. at $0^\circ = 1.0143$. Propionate of baryta is a crystalline compound, $C_3H_5O_2$, BaO, HO. Propionate of silver is anhydrous, $C_3H_5O_2$, AgO.

Ozone and Oxygenated Water.—F. Le Blanc.—Referring to the researches of Thenard on this subject, the author reminds the Academy that, as far back as the year 1854, he arrived at similar results, which were published in the *Comptes Rendus*, 1854, vol. xxxviii., p. 444.

Industrial Application of Ozone in America.—Destruction of the Emphyreumatic Flavour of Whiskey; Manufacture of Vinegar.—M. Wideman.—The author states that in 1869 he established a distillery at Boston, in which ozone was successfully applied for the destruction of fusel oil and emphyreumatic substances contained in raw whiskey, which, when suitably diluted with water, was rapidly converted into vinegar by means of ozone; the quantities of spirits daily operated upon were considerable.

Division of One Base between Several Acids when in Solution; Bibasic Acids.—Dr. Berthelot.—The continuation of the exhaustive monograph on this subject.

Action of Sulphate of Copper upon Normal Urine.—R. de Luna.—By adding to 4 litres of normal urine a rather concentrated solution of sulphate of copper until a blue colouration became permanent, and by filtering and evaporating upon a water-bath the liquid so treated, the author obtained three kinds of crystals, viz., (1) composed of sulphur, oxygen, hydrogen, nitrogen, and phosphorus; (2) containing the same elements, but exhibiting different reactions; (3) containing oxygen, carbon, hydrogen, nitrogen, and traces of iron; lastly, a residue has been obtained which has, in a high degree, the power of reducing salts of copper. All these substances will be the subject of further research.

Noctilucine.—Dr. T. L. Phipson.—We have received this paper from the author; it will appear in our next.

Iodide of Nitrogen.—M. Hussen, jun.—This paper records the results of a series of experiments made by the author with the view of ascertaining the action of starch, gum, and albumen upon iodide of nitrogen in nascent state. The main result is the almost instantaneous decomposition of the iodide of nitrogen and formation of ammonia, according to one of the two following formulae:—

With albumen, a more complex reaction takes place, but the iodide of nitrogen is decomposed and an iodide of albumen formed.

Bulletin de la Société Chimique de Paris, Vol. xviii., No. 1, July 1, 1872.

This number contains the following original papers and memoirs:—

New Experiments on the Isomers of Trichlorhydrine.—Dr. Berthelot.—After first referring to his former experiments on this subject, the author enters into a discussion of the correctness of the experiments of Friedel and Silva as regards the formation of glycerine from a body not originally containing that substance or derived from it. It is pointed out that they started from iodide of allyl, a substance which cannot be prepared without glycerine.

Reply to the Preceding Paper.—C. Friedel and R. D. Silva.—The authors point out that Dr. Berthelot's results do not apply to this case, inasmuch as he fails to prove that there exists a difference between propylene derived from different sources.

Cellulose and Tunicine.—Dr. Berthelot.—By cellulose is now understood that series of carbohydrates, the composition of which is $(C_6H_{10}O_5)_n$, which are converted into glucose by dilute acids, and coloured blue by iodine after previous treatment with either concentrated acids, chloride of zinc, or other substances. These carbohydrates are chiefly distinguished from each other by the amount of their resistance to the action of acids and the oxidising action of potassa, whereby oxalic acid is formed. By tunicine is understood a variety of cellulose which is met with in the envelope of some molluscs; this substance resists the action of chemicals more than cotton or paper, and is not acted upon by fluoride of boron.

Manufacture of Superphosphates.—A. Millot.—This lengthy memoir treats exhaustively on the industrial preparation of superphosphates, and is divided into the following sections:—Use of a mixture of hydrochloric and sulphuric acids; influence of the pulverisation of the mineral phosphates on the formation of reduced phosphates; preparation of superphosphates with bolted mineral phosphates; estimation of reduced phosphate; estimation of phosphoric acid.

Bromated Combinations of Molybdenum.—A. Atterberg.—The author describes—Bromated bromide of molybdenum, $Mo_2Br_4Br_2$, a reddish-yellow coloured infusible powder, insoluble in water and acids, but soluble in alkalis; hydrate of the bromide, $Mo_2Br_4 \cdot 2OH + 3H_2O$, a crystalline gold-yellow coloured body, but, on being heated in a current of carbonic acid, the water is completely driven off; chloride,

$Mo_2Br_4Cl_2 + 3H_2O$, a yellow-coloured amorphous substance; fluoride, $Mo_2Br_4Fl_2 + 3H_2O$; sulphate, $Mo_2Br_4O_8SO_3 + H_2O$; chromate— $Mo_2Br_4O_8CrO_3 + 2H_2O$;
molybdate, $Mo_2Br_4O_8MoO_3 + 2H_2O$; oxalate— $Mo_2Br_4O_8C_2O_3 + 4H_2O$;

phosphate— $Mo_2Br_4O_8 \left\{ \begin{array}{l} 4HO \\ 2PhO \end{array} \right\}$;

cyanide, $Mo_2Br_4Cy_4 + 8KCy$.

Constitution of Tannic Acid.—H. Schiff.—This essay is of great value; it is, however, illustrated by a series of complex formulae, and is not well suited for abstraction.

Chemisches Centralblatt, No. 33, 1872.

This number contains the following original communications:—

Alkaloids of Isopyrum Thalictroides.—F. A. Hartsen.—The root of this plant, belonging to the *Ranunculaceae*, a native of the Lower Pyrenees, contains, according to the author, two different alkaloids, one of which is obtained by boiling the previously cut up root with water, filtration of the decoction, evaporation to the consistency of syrup, and addition of ammonia, whereby a precipitate is formed, consisting of tannin and hydrate of alumina; this precipitate, having been dried, yields, after treatment with ether and evaporation of that fluid, an amorphous powder of a whitish-yellow colour; this is the alkaloid termed isopyrin, which yields with hydrochloric acid an amorphous salt not precipitated by chloride of ammonium. Another alkaloid is obtained from the root; after first boiling it with water, and next treating it with alcohol, the alcoholic solution is evaporated, and to the residue, ammonia is first added, and then ether, by the evaporation of which a crystalline substance is left, which the author terms pseudo-isopyrin; the chlorine compound of this body is precipitated by chloride of ammonium from its aqueous solution. The author intends to continue his researches on these substances.

Stearopten of the Flowers of Clandestina Rectiflora.—F. A. Hartsen.—These flowers are those of a parasitical plant which lives on poplar and willow trees, more especially on the roots, and is a native of Southern France; from the buds of these flowers, the author has obtained, by treatment with ether, a stearopten, soluble in ether and alcohol, insoluble in water, and sublimable like camphor. This substance the author provisionally terms clandestinin; the researches on the nature of this body are to be continued.

No. 34, 1872.

This number contains the following original communications:—

Chloroform from Pure Methyl Alcohol.—A. Belohonek.—The author states that when pure methyl alcohol is treated with bleaching-powder and distilled water, no chloroform is produced; the reason why commercial methyl alcohol yields chloroform is that it contains impurities in large quantity. Neither oxalate of methyl or acetic acid yield chloroform with an aqueous solution of bleaching-powder.

Nicotin.—H. Weidl.—This alkaloid yields, with nitric acid, nicotinic acid, $C_{10}H_7N_2O_6$, a solid crystalline body, which, when heated with lime, yields pyridin, C_5H_5N . The acid is, according to the author, identical with that which Huber has obtained from nicotin by oxidation with chromic acid. While making some preliminary observations on the structure of nicotin and the acid obtained from it, the author states that nicotin may be prepared from the aldehyde of pyrotartaric acid, in the same manner as aldehydin (isomeric with collidin) from the aldehyde of crotonic acid—

Aldehyde of crotonic acid. Aldehydin.

Aldehyde of pyrotartaric acid. Nicotin.

Lichen Spirits.—Dr. R. Arendt.—It appears that the original Swedish discovery of utilising the mosses and lichens, so abundantly met with in Northern Europe, for the preparation of brandy and alcohol, is now largely carried on in the Russian provinces of Archangel, Pakow, Nowgorod, and others. At the late Russian Industrial Exhibition at Moscow several samples of moss spirits were exhibited by various distillers, and the quality of this brandy was generally highly approved of by foreigners, and especially Englishmen and Frenchmen. This industry is lucrative, for it yields in the more northern provinces of Russia a net revenue varying from 40 to 120 per cent.

Jahrbuch der Kaiserlich-Königlichen Geologischen Reichsanstalt, No. 2, 1872.

This number contains no original papers relating to chemistry and the appendix, *Mineralogische Mittheilungen*, contains analyses of minerals of interest only to the Austro-Hungarian empire; we give the titles, however, of the following essays:—

Meteorites of Stannern, Constantinople, Shergotty, and Gopalpur.—G. Tschermak.

Rocks of the Caucasus.—G. Tschermak.

Microscopical Structure of the Lava of Vesuvius.—September, 1871; March and April, 1872.—A. v. Inostranetz.

Journal für Praktische Chemie, Nos. 11 and 12 (double number), 1872.

This number contains the following original papers and memoirs:—

Contribution to our Knowledge of the Physiological Chemistry of Milk.—Dr. F. Soxhlet.—This monograph is divided into the following sections:—Relation of the alkaline phosphates to the alkaline albuminate (*Alkalialbuminat*); reaction of milk and of other animal fluids; coagulation of milk by rennet; filtration (*Filterbarkeit*) of casein through porous earthenware; capability of milk of being precipitated by carbonate of soda; relation of casein and of albuminate to a caustic alkaline lye; circumplarisolation of casein and of potassa albuminate (*Kalialbuminat*).

Chemical Investigation of the Mineral Waters at Bad Ems (Nassau, Prussia).—Dr. R. Fresenius.—The first portion of this memoir contains the record of the author's researches of the water of the source known as Das Kränchen; the temperature of this water appears to vary, and has apparently increased since 1838, when it was found by Kastner to be 26°4'R., while the author found it, on October 7, 1871, to be 28°48'R.; the sp. gr., taken at 16°9', is 1'00308; the average yield is about 2700 litres in twenty-four hours. The following substances, detected in the water, are not present in sufficient quantity to admit of being weighed:—Boric acid, combined with soda; cesium and rubidium, combined with sulphuric acid; fluorine, combined with calcium; a trace of nitrogen gas. This water also contains, in 1000 parts:—Bicarbonate of soda, 1'999016; bicarbonate of lithia, 0'000407; bicarbonate of ammonia, 0'002352; sulphate of soda, 0'0033545; chloride of sodium, 0'983129; bromide of sodium, 0'000340; iodide of sodium, 0'000022; phosphate of soda, 0'001459; sulphate of potassa, 0'0036773; bicarbonate of lime, 0'216174; bicarbonate of strontia, 0'002343; bicarbonate of baryta, 0'001026; bicarbonate of magnesia, 0'206985; bicarbonate of protoxide of iron, 0'001989; bicarbonate of protoxide of manganese, 0'000173; phosphate of soda, 0'000116; silica, 0'049742; quite free (*Volligfrei*) carbonic acid, 1'039967—total of all constituents, 4'559198. At 35°86', which is the normal temperature of the water, and at normal barometer reading, 1000 c.c. of the water contain 597'48 c.c. of quite free carbonic acid and 404'20 c.c. of semi-combined carbonic acid. Der Fürstenbrunnen.—Temperature of the water, 32°30' R. = 40°40' C.; sp. gr., 1'00333; yield in twenty-four hours, 3389 litres. 1000 parts of this water contain:—Bicarbonate of soda, 1'995607; bicarbonate of lithia, 0'000439; bicarbonate of ammonia, 0'002510; sulphate of soda, 0'0017060; chloride of sodium, 1'011034; bromide of sodium, 0'000350; iodide of sodium, 0'000022; phosphate of soda, 0'001467; sulphate of potassa, 0'048512; bicarbonate of lime, 0'217079; bicarbonate of strontia, 0'002477; bicarbonate of baryta, 0'001030; bicarbonate of magnesia, 0'205565; bicarbonate of protoxide of iron, 0'001897; bicarbonate of protoxide of manganese, 0'000181; phosphate of alumina, 0'000117; silica, 0'049953; carbonic acid, 1'029536—total of all constituents, 4'629776. Free and semi-combined carbonic acid, together, in 1000 c.c. of the water, 1026'2 c.c., of which 599'35 c.c. are quite free CO₂. Der Kesselbrunnen.—Temperature of water of this source, 37°31° R. = 46°64° C.; sp. gr. of water at 17°, 1'003028; yield in twenty-four hours, 28,800 litres. 1000 parts contain:—Bicarbonate of soda, 1'989682; bicarbonate of lithia, 0'005739; bicarbonate of ammonia, 0'007104; sulphate of soda, 0'015554; chloride of sodium, 1'031306; bromide of sodium, 0'000454; iodide of sodium, 0'000035; phosphate of soda, 0'000490; sulphate of potassa, 0'043694; bicarbonate of lime, 0'219605; bicarbonate of strontia, 0'001815; bicarbonate of baryta, 0'001241; bicarbonate of magnesia, 0'182481; bicarbonate of protoxide of iron, 0'003258; bicarbonate of protoxide of manganese, 0'000330; phosphate of alumina, 0'000200; silica, 0'048540; carbonic acid (quite free), 0'93071—total, 4'4817175. 1000 c.c. of this water contain 980'8 c.c. of free and semi-combined carbonic acid, of which 553'14 c.c. are quite free. Die neue Badequelle.—Temperature of the water of this source, 40°05° R. = 50°04° C.; sp. gr. at 17°, 1'00300. 1000 parts of this water contain:—Bicarbonate of soda, 2'052767; bicarbonate of lithia, 0'005536; bicarbonate of ammonia, 0'008215; sulphate of soda, 0'041500; chloride of sodium, 0'927149; bromide of sodium, 0'000480; iodide of sodium, 0'000004; phosphate of soda, 0'000368; sulphate of potassa, 0'044151; bicarbonate of lime, 0'220435; bicarbonate of strontia, 0'001516; bicarbonate of baryta, 0'000981; bicarbonate of magnesia, 0'210350; bicarbonate of protoxide of iron, 0'003985; bicarbonate of protoxide of manganese, 0'000334; phosphate of alumina, 0'000209; silica, 0'047472; quite free carbonic acid, 0'746261—total, 4'311707. The quantity of carbonic acid by bulk (at 50°04° and normal barometer) amounts, in 1000 c.c. of the water, to 897'97 c.c., of which 448'5 c.c. are quite free. The substances present in unweighable quantity in the three last-mentioned sources are the same as those mentioned in the Kränchen, but the Kesselbrunnen and Neue Badequelle contain, in addition, some traces of sulphuretted hydrogen.

Some of the Gases Occluded in Braunkohlen.—Dr. H. Kolbe.—This is a preliminary notice. The author found in Bohemian braunkohlen the under-mentioned percentage quantities of gases:—

	CO ₂	CO	N	O
I.	89'66	1'80	8'03	0'51
II.	82'40	3'00	14'15	0'45
In earthy braunkohlen . .	83'99	1'04	14'91	0'65

Guadalazarite, a New Mineral.—T. Petersen.—The name of this mineral is derived from Guadalcazar (Mexico). Its sp. gr. at 15° is 7'15; its composition, in 100 parts, is:—Sulphur, 14'58; selenium, 1'08; mercury, 79'73; zinc, 4'23; cadmium, a trace; iron, a trace—total, 99'62. Formula, 6HgS + 2ZnS.

Some Thallium Compounds.—Dr. S. M. Jørgensen.—This monograph contains a detailed description of the following substances:—Thallium-iodide; cuprotetrammonium-thallium iodide; thallium protochloride-mercuric chloride; tetrethylphosphonium-thallium iodide; triethylsulphin-thallium iodide; tarconium-thallium iodide.

Asparaginic Acid, a Product of the Oxidation of Conglutin when Acted upon by Permanganate of Potassa.—Dr. R. Pott.—After first referring to his researches on conglutin (*Journ. f. Prakt. Chem.*, [2], vol. v., p. 355), the author records at length his method of operating, the result of which is that, although only in small quantity, he obtained asparaginate of copper, C₈H₇CuNO₄, by treating conglutin with permanganate of potassa, and combining the asparaginic acid with copper by means of the carbonate of that metal.

Chlorides of Carbon.—K. Hoch.—Only the first page of this paper is published; the paper will therefore be abstracted when complete.

Journal für Gasbeleuchtung und Wasserversorgung, No. 13, 1872.

This number only contains papers and memoirs strictly relating to gas- and water-works' engineering and management.

No. 14, 1872.

Peculiar Case of Gas-Leakage and Poisoning by Gas.—H. F. Ziegler.—This memoir, illustrated by a map exhibiting the situation of the houses, gas-mains, service-pipes, syphons, and course of a portion of a street in Hanau, contains a detailed account of a serious leakage of gas from a syphon fitted to an 8-inch main, and the infiltration of that gas through the soil, so that a person sleeping in one of the houses was nearly suffocated, but respiration was restored after several hours by the application of oxygen. Very many years ago a similar case happened at Strasburg, a full record of which has been published by the late Dr. Orfila.

La Revue Scientifique de la France et de l'Etranger, August 31, 1872.

This number contains no original papers relating to chemistry, but the lectures on general physiology are continued:—

Phenomena of Life which are common to Animals and Plants.—Dr. C. Bernard.—This portion treats at great length on animal glycogenesis.

French Association for the Advancement of Sciences.—The complete programme is here published; it comprehends the following sections:—(1) Mathematics, astronomy, and geodesy. (2) Mechanics. (3) Navigation. (4) Civil and military engineering. (5) Natural philosophy. (6) Chemistry.—Berthelot, questions of chemical philosophy; Friedel, study of some instances of isomerism in the compounds with three atoms of carbon; A. Gautier, on some new phosphorus compounds; Grimaux, on the constitution of the monobasic fatty acids; Gruner, on steel; Henninger, synthesis of orcin; Jungfleisch, conversion of tartaric into para-tartaric acid; Prat, on the diffusion of selenium; Prat, on the theory of fluorine; Prat, on the estimation of phosphates in general; Saint Loup, on a contrivance suitable for the production of ozone and for the study of its properties; Schützenberger, on phospho-platinic compounds; Arnaud-Thénard, new facts relating to oxygenated water (peroxide of hydrogen) and ozone; Wurtz, on anomalous vapour densities, and more especially the vapour of perchloride of phosphorus. (7) Meteorology and physical condition of the globe. (8) Geology and mineralogy. (9) Botany. (10) Zoology and zootechny. (11) Anthropology. (12) Medical sciences. (13) Agronomy. (14) Geography. (15) Political economy and statistics. The excursions will be seven, and will extend as far as Bidassoa on the Spanish frontier. Among the subjects on which public lectures will be held we notice the following:—Fermentation, by Pasteur; aerial navigation, by Dupuy de Lôme; industry of the landes of Gascogne, by Chambrelent.

Les Mondes, August 29, 1872.

This number contains no original papers relating to chemistry; there is, however, a paper entitled—

Prehistoric Times in Belgium.—F. Plateau.—An excellent and clear *résumé* of the labours of the International Congress of Anthropology, which has just concluded its meeting at Brussels, and a full review of all that belongs to the quaternary geological period; it appears that in Belgium many interesting objects elucidating the prehistoric age of man have been found.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 237, September, 1872.

Application of Electricity to a Débrayeur (a Mechanism to Throw out of Gear).—M. Richard.—A report, illustrated by several engravings, on a contrivance by which the breaking of threads in the process of weaving may be prevented to some extent.

Practical Irrigation—Canal de Lestelle (Haute Garonne).—H. Tranié.—The great utility of irrigation of arable and meadow lands is explained in this memoir by the detailed account of a comparatively small engineering work, constructed by the author for several landed proprietors in the locality alluded to; by judiciously arranged irrigation the net revenue per hectare (2'47 acres) has been increased by £11 15s.

Relation of the Eye and the Ocular Glasses chiefly in Use in Optical Instruments; Description of an Apparatus for Testing the Ocular Glasses.—F. P. Le Roux.—An exhaustive optico-algebraical essay, illustrated by several woodcuts.

Aérostation—Directing the Course of Air-Balloons; Limits of the Problem.—Ch. Laboulaye.—An exhaustive monograph, illustrated by several engraved plates; this paper contains complete and detailed information on Dupuy de Lôme's experiments and aerostatic journeys.

NOTES AND QUERIES.

Gum Copal.—I should feel grateful if any of your readers could inform me how to purify gum copal from the attached impurities which occur with it as imported. I have tried solution in methylated spirits and oil of turpentine, and then distillation, but the gum is imperfectly soluble in these liquids. I have also tried distillation in a current of steam, but the distillate is a soft sticky mass of a yellow colour. What is wanted is to cleanse the gum from the attached dirt, without loss of gum or alteration of properties.—C. T. KINGZETT.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents,
54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2328. E. Packard, jun., Ipswich, "Improvements in the manufacture of superphosphate of lime and artificial manure."—Petition recorded August 3, 1872.
2334. J. Deere, Briton Ferry, Glamorganshire, "Improvements in the manufacture of artificial fuel."—Petition recorded August 5, 1872.
2344. C. Morfit, Baltimore, Ma., U.S.A., "Improvements in the chemical treatment of mineral and other crude phosphates of lime."—Petition recorded August 7, 1872.
2357. C. Morfit, Ma., U.S.A., "An artificial substitute for 'Redonda guano,' Alta Vela, guano, and other natural phosphates of alumina, to be used in the defecation of sewage, in the manufacture of sugar from cane and beet-root juices, and in the preparation of certain chemical products, such as pure alumina, and the alkaline and earthy phosphates and aluminates."—Petition recorded August 8, 1872.
2299. J. Richardson, Brookfoot, near Brighouse, Yorks., "Improvements in the process of dyeing textile fabrics."—Petition recorded August 12, 1872.
2405. A. M. Clark, Chancery Lane, "A new or improved medicinal compound."—A communication from C. V. Viard, Paris.—Petitions recorded August 12, 1872.
2417. F. D. Blyth, London, and A. G. Southby, New Inn, Middlesex, "Improvements in the process and apparatus for treating wood for the manufacture of pulp for paper."—Petition recorded August 14, 1872.
2426. D. Joy, Saltburn-by-the-Sea, Yorkshire, "Improvements in the means and apparatus for purifying iron, and for removing the slag and other impurities from blast and other furnaces."—Petitions recorded August 14, 1872.
2431. T. Koutledge, Ford Works, near Sunderland, "Improvements in heating fibrous substances for textile purposes, and for the manufacture of paper stock."—Petition recorded August 17, 1872.
2434. L. D. B. Gordon, Totteridge, Herts., "Improvements in the manufacture of iron and steel."—A communication from Professor Scheerer, Freyburg, Saxony.
2443. W. R. Lake, Southampton Buildings, London, "Improvements in puddling furnaces."—A communication from G. E. Harding, New York, U.S.A.—Petitions recorded August 15, 1872.
2446. A. K. Arrott, St. Helens, Lancashire, "Improvements in the manufacture of carbonate of soda."—Petition recorded August 16, 1872.
2459. G. P. Dodge, Upper Thames Street, London, "An improved cement for the joints of pipes and other apparatus for containing or conducting steam, water, or other fluids."—Petition recorded August 17, 1872.
2487. W. Young, Magdalen Bridge, P. Brash, Leith, and A. Scott, Musselburgh, Midlothian, "Improvements in the destructive distillation of coal, shale, and other bituminous substances for the production of illuminating gas, and of oils."—Petition recorded August 21, 1872.

NOTICES TO PROCEED.

1240. H. Galm, Upsala, Sweden, "Improvements in cosmetics."—Petition recorded August 21, 1872.
1243. S. W. Rich, Chancery Street, Middlesex, "Improvements in the manufacture of sulphates."—Petitions recorded April 25, 1872.
1699. J. T. Dann, North Brixton, Surrey, "Improvements in the manufacture of phosphorus."—A communication from G. F. Féron, Rouen, France.—Petition recorded June 5, 1872.
2277. E. P. H. Vaughan, F.C.S., Chancery Lane, "Improvements in the treatment of phosphates of lime."—A communication from A. Striedter, Paris, France.—Petition recorded July 30, 1872.
2389. H. A. Bonneville, Paris, France, "A new or improved process of manufacturing cast-steel."—A communication from H. A. Levallois, Paris, France.—Petition recorded August 10, 1872.

PATENTS SEALED.

573. R. Elsdon, Brockham, Surrey, "Improvements in the conversion of cast-iron into steel or wrought-iron, and in the apparatus employed therein."—Dated February 22, 1872.
653. E. Powers, Coventry, Warwickshire, "Improvements in the manufacture of iron, steel, copper, and other metals."—Petition recorded March 2, 1872.
656. J. P. R. Poch, Brussels, Belgium, "A new chemical compound for blasting purposes."—Dated March 2, 1872.
671. R. Blackburn, Exeter, Devon, "Improvements in apparatus and in means for treating sewage for agricultural purposes."—Dated March 5, 1872.
685. C. D. Abel, Southampton Buildings, Middlesex, "Improvements in the manufacture of Bessemer steel and iron, and in the production of iron castings, and in apparatus therefor."—A communication from Z. S. Durfee, New York, U.S.A.—Dated March 6, 1872.

774. W. J. Lockyer, Bristol, "Improvements in the preparation of artificial manures."—Dated March 14, 1872.

801. F. W. Gerhard, Wolverhampton, and J. Light, jun., Bradley, Staffordshire, "Improvements in the production of iron and steel."—Dated March 16, 1872.

890. R. M. Letchford and W. B. Nation, Bethnal Green, Middlesex, "Improvements in the treatment of paraffin."—Dated March 23, 1872.

1032. A. M. Clark, Chancery Lane, Middlesex, "Improvements in the manufacture of illuminating gas and in apparatus for the same."—A communication from F. M. Rouillé, Boulevard St. Martin, Paris.—Dated April 6, 1872.

1215. J. W. Gray, Billiter Street, London, "A new or improved lithoidal composition to be used as a paint and for other purposes."—A communication from F. Renoz, Liège, Belgium.—Dated April 23, 1872.

1566. J. Jeyes, Plaistow, Essex, "An improved fuel."—Dated May 17, 1872.

1637. C. Moseley, Ardwick, Manchester, "A new method and means for condensing the vapours of coal-tar naphtha."—Dated May 30, 1872.

1657. D. Nicoll, St. Paul's Churchyard, London, "Improved preparations applicable to woven and other fabrics for the purpose of rendering the same unflammable."—Dated May 31, 1872.

1699. C. W. Harrison and A. H. Harrison, High Holborn, Middlesex, "Improvements in the manufacture of gas for lighting and heating purposes, and in the apparatus employed therein."—Dated June 3, 1872.

1806. W. C. Sillar, Blackheath, Kent, R. G. Sillar, Bolton, Lancashire, and C. Rawson, St. Swithin's Lane, London, "Improvements in treating animal matters in order to deodorise and decompose the same and to make a manure therefrom."—Dated June 15, 1872.

1851. V. Van Baerle, Worms, Germany, "Improvements in the manufacture of soap or compositions for washing purposes."—Dated June 19, 1872.

1892. G. A. Dorsett, Rotherhithe, Surrey, "Improvements in obtaining anthracene from heavy oils."—Dated June 22, 1872.

1964. B. Russ, Lime Street, London, "Improvements in the manufacture of gas, and in the treatment of residues therefrom, in the means of purifying and redifying the same; and in the combination or amalgamation of gases for the production of light and heat, and for other useful purposes, and in the machinery and apparatus to be employed therein."—Dated June 29, 1872.

2077. W. Gorman, Glasgow, N.B., "Improvements in manufacturing iron and steel, and in apparatus connected therewith, part or parts of such improvements being applicable to various kinds of furnaces, and for the production of gases for heating and illuminating purposes, and for coking, carbonising, or calcining other substances."—Dated July 4, 1872.

THE CHEMICAL NEWS.

VOL. XXVI. No. 668.

(STUDENTS' NUMBER.)

SCHOOLS OF CHEMISTRY.

EXAMINING BOARDS.

UNIVERSITY OF LONDON.

CANDIDATES for any Degree granted by this University are required to have passed the Matriculation Examination, to which no candidate is admitted unless he has produced a certificate showing that he has completed his sixteenth year.

The Fee for this Examination is £2.

The Examination will be held on Monday, January 13th, 1873, and includes the following subjects:—

NATURAL PHILOSOPHY.*

Mechanics—

Composition and Resolution of Statical Forces.

Simple Machines (*Mechanical Powers*): Ratio of the Power to the weight in each.

Centre of Gravity.

General laws of Motion, with the chief Experiments by which they may be illustrated.

Law of the Motion of Falling Bodies.

Hydrostatics, Hydraulics, and Pneumatics—

Pressure of Liquids and Gases, its equal diffusion, and variation with the depth.

Specific Gravity, and modes of determining it.

The Barometer, the Syphon, the Common Pump and Forcing-Pump, and the Air-Pump.

Acoustics—

Nature of Sound.

Mode and Rate of Propagation of Sound.

Musical Tones.

Optics—

Laws of Reflection and Refraction.

Formation of Images by Simple Lenses.

CHEMISTRY.

Heat—its sources. Expansion. Thermometers—relations between different Scales in common use. Difference between Temperature and Quantity of Heat. Specific and Latent Heat. Calorimeters. Liquefaction. Ebullition. Evaporation. Conduction. Convection. Radiation.

Chemistry of the Non-Metallic Elements; including their compounds as enumerated below—their chief physical and chemical characters—their preparation—and their characteristic tests.

Oxygen, Hydrogen, Carbon, Nitrogen. Chlorine, Bromine, Iodine, Fluorine. Sulphur, Phosphorus, Silicon.

Combining Proportions by weight and by volume. General Nature of Acids, Bases, and Salts. Symbols and Nomenclature.

The Atmosphere—its constitution; effects of Animal and Vegetable Life upon its composition.

Combustion. Structure and Properties of Flame, Nature and Composition of ordinary Fuel.

Water. Chemical peculiarities of Natural Waters, such as rain-water, river-water, spring-water, sea-water.

Carbonic Acid. Carbonic Oxide, Oxides and Acids of Nitrogen. Ammonia. Olefiant Gas, Marsh Gas, Sulphurous and Sulphuric Acids, Sulphuretted Hydrogen.

* The Questions in Natural Philosophy will be of a strictly elementary character.

Hydrochloric Acid. Phosphoric Acid and Phosphoretted Hydrogen. Silica.

BACHELOR OF SCIENCE (B.Sc.)

This degree is conferred on candidates who pass a satisfactory examination in Mathematics, Mechanical and Natural Philosophy, Botany, and Vegetable Physiology, Zoology, and Chemistry.

FIRST B.Sc. EXAMINATION.

No candidate (with the exception of such as have obtained Honours at the Matriculation Examination in the preceding January) is admitted to this examination within one academical year of the time of his passing the Matriculation Examination.

The Fee for this Examination is £5.

The examination will commence on the third Monday in July. It is conducted by means of printed papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the candidates to pass, *viva voce* questions to any Candidate in the subjects in which they are appointed to examine.

The First Examination includes the following subjects:—

NATURAL PHILOSOPHY.

Heat—

Sources of Heat; conduction—convection.

Effects of Heat; expansion generally—of water—of gases and vapours; liquefaction; vaporisation; latent heat; expansive form of steam; dew-point; gases and vapours compared.

Specific Heat.

Thermometers; Pyrometers.

Heat in the Radiant state.

Electricity—

Sources of Electricity.

Static Electricity; dual character—insulation—induction—specific inductive capacity—equivalent antithetic states—disruptive discharge—convection; Electroscopes—Leyden Jar, &c.

Dynamic Electricity; Conduction—the electric current—derived currents—induction of currents; Voltaic Pile and other voltaic arrangements.

Thermo-Electricity; Electro-Thermometer.

Magnetism—

Magnets, the Earth, &c.; Induction—communication—retention—Magnetic relations of iron, steel, &c.

Electro-Magnetism—as in the spark—in conducting media—in soft iron; Magneto-Electricity; principle of Electro-magnetic and Magneto-Electric machines.

Terrestrial Magnetism.

INORGANIC CHEMISTRY.

Matter; simple and compound.

Elementary bodies classed. Metallic and Non-Metallic bodies.

Chemical combination and Mechanical Mixture. Solution.

Outlines of Crystallography. Isomorphism. Dimorphism. Allotropic conditions of matter. Chemical Affinity. Laws of Combination by weight and by volume, as deduced from the history of the individual elements. Equivalent Numbers. Equivalent Volumes. Symbolical Notation, including questions on the Unitary System. Formulæ. Nomenclature.

Chemical actions produced under the influence of Heat. Nature of Combustion. Structures and Properties of Flame. Principles of Illumination. Chemical action of Light. Photography.

Oxygen. Ozone.

Hydrogen. Water.

Nitrogen. Chemical constitution of the Atmosphere. Diffusion of Gases. The Oxides of Nitrogen; Nitric Acid. Ammonia.

Chlorine, Bromine, and Iodine. Their compounds with Oxygen and Hydrogen. Theory of Bleaching. Fluorine and Hydrofluoric Acid.

Sulphur, Sulphurous Acid. Manufacture and Chemical applications of Sulphuric Acid. Other Oxygen compounds of Sulphur. Sulphuretted Hydrogen.

Phosphorus. Oxygen and Hydrogen compounds of Phosphorus. Theory of Acids. Monobasic, Dibasic, and Tribasic Acids.

Carbon. Carbonic Oxide and Carbonic Acid. The principal Hydrogen compounds of Carbon. Manufacture of Coal Gas.

Silicon and Boron. Their compounds with the elements previously enumerated.

Metals. Characters of Metals as a class. Metallurgical Processes. Alloys. Classification of the Metals.

Potassium. Nitre. Gunpowder. Theory of the action of Gunpowder.

Sodium. Manufacture of Carbonate of Soda. Barium. Strontium. Calcium. Mortars. Cements.

Magnesium. Aluminum. Glass. Porcelain. Manganese. Iron. Composition and properties of Cast-

Iron, Wrought-iron, and Steel. Chromium. Cobalt. Nickel. Zinc. Cadmium.

Lead. Manufacture of White-Lead. Copper. Mercury. Bismuth. Tin. Arsenic. Antimony. Silver. Gold. Platinum.

Principal compounds of the Metals with the Non-Metallic Elements. Theory of Salts.

Principles of Mineral Analysis. Principles of Electro-Chemistry.

For the First Examinations, a knowledge of Inorganic Chemistry only is necessary.

EXAMINATION FOR HONOURS.

Candidates for Honours in Chemistry are examined in any of the following subjects, at the option of the Examiners:—

Elementary Substances and their combinations.

Electro-Chemistry.

Radiant Chemical Action.

In the Examination for Honours, the Candidate, being not more than twenty-two years of age, who most distinguishes himself in Chemistry and Natural Philosophy, will receive an Exhibition of Forty pounds per annum for the next two years.

SECOND B.Sc. EXAMINATION.

This Examination commences on the fourth Monday in October. Candidates for this Examination who have not previously taken the degree of B.A. are required either to have passed the First B.Sc. Examination at least one Academical year previously, or to have passed the First M.B. Examination in this University.

The Fee for this Examination is £5.

This Examination embraces Organic Chemistry, including the following subjects:—

Ultimate Analysis of Organic bodies. Calculation of Empirical Formulæ. Methods of controlling Empirical Formulæ. Determination of the Equivalents of organic acids and bases; examination of products of Decomposition; determination of the Vapour-density of volatile bodies.

Law of Substitution. Compound Radicals. Homologous Series.

The Chemical History of the Cyanogen group. Cyanogen. Hydrocyanic Acid. Cyanic Acid and Urea. Fulminates. Cyanuric Acid. Sulphocyanic Acid. Chlorides of Cyanogen. Uric Acid.

Amylaceous and Saccharine Substances. Fermentation. Alcohol, Wine, Beer, Bread, &c.

Homologues of Alcohol. Ethers, simple and mixed. Oxidation of Alcohol. Aldehyde and Acetic Acid, and their homologues. Anhydrides, simple and mixed. Compound Ethers.

Diatomic Alcohols and their Acids. Glycol and Oxalic Acid and their homologues.

Triatomic Alcohols. Glycerine. Fatty and Oily bodies. Saponification.

Vegetable Acids;—the principal.

Ammonia and its Derivatives. Ammonium and Ammoniacal Salts. Amides and Amines; their Classification. The chief Natural Organic Bases.

Colouring Matters. Indigo and its derivatives. Principles of Dyeing.

The chief constituents of the Vegetable organism. Cellulose, Vegetable Fibrin, Albumen, Casein, Glutin, &c.

The chief constituents of the Animal organism. Animal Fibrin, Albumen, Casein, Gelatin. Blood, Milk, Bile, Urine, &c.

Decay, Putrefaction. Destructive Distillation. The Chemical Principles of the process of Nutrition and of Respiration in Plants and Animals.

EXAMINATION FOR HONOURS.

The Candidate, not more than twenty-three years of age, who, in the Examination for Honours, most distinguishes himself in Chemistry, will receive Fifty pounds per annum for the next two years, with the title of University Scholar.

DOCTOR OF SCIENCE (D.Sc.).

This Examination is held within the first twenty-one days of June, and occupies four days.

No Candidate is admitted to the Examination for the Degree of D.Sc. until after the expiration of two Academical years from the time of his obtaining the Degree of B.Sc. in this University.

Candidates for the Degree of D.Sc. in any year, must give notice of their intention to the Registrar, and pay to him a Fee of Ten pounds, on or before the 1st of April.

Chemical Candidates can be examined either in Inorganic or Organic Chemistry; but no Candidate will be approved by the Examiners unless he has shown a thorough practical knowledge* of the *Principal Subject*, and a general acquaintance with the *Subsidiary Subject*, or *Subjects*, specified as belonging to the Branch so selected.

Inorganic Chemistry.

Principal Subject—Inorganic Chemistry.

Subsidiary Subjects—Either Organic Chemistry; or, Mineralogy, Crystallography, and Chemical Technology in its relations to Inorganic Chemistry.

Organic Chemistry.

Principal Subject—Organic Chemistry.

Subsidiary Subjects—Either Inorganic Chemistry; or, Chemical Technology, in its relations to Organic Chemistry, and the Chemistry of Animal and Vegetable Life.

EXAMINATIONS IN CONNECTION WITH THE DEPARTMENT OF SCIENCE AND ART, SOUTH KENSINGTON.

A sum of money is voted annually by Parliament for scientific instruction in the United Kingdom.

This sum is administered by the Science and Art Department.

The object of the grant is to promote instruction in Science, especially among the Industrial classes, by affording a limited and partial aid or stimulus towards the founding and maintenance of Science schools and classes.

The following are among the Sciences towards instruction in which aid is given:—Acoustics, Light, Heat, Magnetism, and Electricity, Inorganic Chemistry, Organic Chemistry, Geology, Mineralogy, Mining, Metallurgy.

The assistance granted by the Science and Art Department is in the form of—1. Public Examinations, in which Queen's Medals and Queen's Prizes are awarded, held at all places complying with certain conditions. 2. Payments on results to teachers. 3. Scholarships and Exhibitions. 4. Building Grants. 5. Grants towards the purchase of apparatus, &c.

* It must be understood that the candidate for the Degree of D.Sc. is expected to be so fully conversant with the principal subject he may select, as to be able to go through any examinational test (whether theoretical or practical) of his acquirements in it that can be fairly applied.

CHEMICAL LECTURES AND LABORATORY INSTRUCTION.

UNIVERSITY COLLEGE.

FACULTY OF SCIENCE.

Dean.—Professor J. B. Sanderson, M.D., F.R.S.

Vice-Dean.—Professor A. W. Williamson, Ph.D., F.R.S.

The Session begins on Wednesday, the 2nd of October, and ends on Friday, the 20th of June.

It is divided into three Terms, as follows:—Michaelmas term, from October 2nd until December 14th; Lent term, from January 6th, 1873, till March 18th; Summer term, for Lectures, from March 19th till June 11th, all inclusive.

Chemistry.—Professor Williamson, Ph.D., F.R.S.

A. GENERAL COURSE.

Lectures daily, except Saturday, from 11 to 12 a.m., up to the last week in March.

Exercises on Tuesdays, Wednesdays, Thursdays, and Fridays, from 9 to 10 a.m.

Fee for the Whole Course of Lectures, £7 7s.; for the First or Second Half Course, separately, £4 4s.; for the Second Half when the First has been taken, £3 3s.; Perpetual, £9 9s.; for the Organic Course alone, £2 2s.

Fee for the Exercise-Class—For the Course, £2 2s.; for the Half Course, £1 1s.

The Instruction in this Class is of two kinds, consisting partly of Experimental Lectures by the Professor, partly of Exercises and personal instruction on the subject of the Lectures by Tutors, under the direction of the Professor.

Students cannot profit duly by attendance on the Lectures, unless they work at the subject of each Lecture so as to make it their own.

Attendance on the tutorial part of the Class enables Students to do their work more effectually and rapidly than they can do it by themselves.

The First Half of the Course to Christmas includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

The Second Half of the Course, from January to March, includes the following subjects:—

I. Preparation and properties of the chief metals, including their characteristic reactions and most important salts. Detection of Metallic Poisons. Quantitative Estimation of Metals. Principles of Classification. Monatomic, Diatomic Metals, &c.

A weekly *viva voce* examination is held during the First Half Course and the commencement of the second Half Course.

Organic Chemistry.

This commences in the second week in February, and occupies Five Lectures weekly till about the end of March. It includes a study of the characteristics and metamorphoses of the chief organic acids, bases, alcohols, ethers, colouring matters, &c. Methods of ultimate and proximate analysis. Determination of molecular weights. Theory of types; of compound radicals. Phenomena of fermentation, &c.

Teachers of Chemistry are trained in the theory and practice of their profession. A two years' Course is absolutely requisite for this purpose; but Students will with advantage devote a longer period to it.

The first year is occupied with attendance on the Courses of Chemistry and of Analytical Chemistry. In the second year the Student again attends the Course of Chemistry, and is entrusted with teaching work in conjunction with the Tutors of the Class. At the same time he continues to work in the Laboratory at analysis and original research.

In order to qualify themselves for rising to the higher ranks of the Profession, gentlemen remain for a further period, in which case they may obtain remunerative work in teaching through the recommendation of the Professor.

It must not, however, be supposed that a study of Chemistry alone, however complete, is sufficient to qualify a man to teach the Science effectively. A competent

knowledge of Physics, Mathematics, and either French or German must necessarily be acquired at some period of his Student's Course.

B. ANALYTICAL AND PRACTICAL CHEMISTRY.

I. BIRKBECK LABORATORY.

The instruction in the Laboratory is intended for beginners as well as for more advanced students. It includes practice in the construction and use of apparatus for preparing the common gases, acids, bases, salts, &c.; study of the qualitative methods of detecting and separating mineral or organic bodies from one another; also quantitative analysis in the wet way, organic analysis, vapour-densities, &c.; instruction in gas analysis.

More advanced Students are instructed in the methods of original research, especially in organic chemistry.

When accompanied or preceded by attendance on the Lectures on Chemistry, the Laboratory Course qualifies Students in the application of Chemistry to the Manufacturing Arts, Metallurgy, Medicine, or Agriculture, &c. Instruction is given in the principles and processes of Gas Analysis.

The Laboratory and Offices are fitted up completely with the most improved apparatus and utensils for experimental research, both for beginners and for advanced Students. They are open daily, from 9 a.m. to 4 p.m., from the 4th of October until the end of July, with a short recess at Christmas and at Easter. Saturday, from 9 to 2.

Fees for the Session, 25 guineas; six months, 18 guineas; three months, 10 guineas; one month, 4 guineas; exclusive of the expense of materials. A deduction of about 40 per cent is made for students who can attend only three fixed days per week.

A Gold Medal and Certificates of Honour are competed for by Students entered for the Session.

II. SUMMER COURSES.

I. Elementary Course.

About Forty Lessons, of one hour each, on Tuesday, Wednesday, Thursday, and Friday, from 11 to 12, commencing in the first week of May. Students are taught the construction and use of apparatus for the preparation of the most important gases, acids, &c. The characteristic tests for the presence of the common acids and bases, including the chief metallic and other poisons. Also the processes for separating these bodies from one another.

Solutions are frequently given in the class for investigation.

The first six weeks of the Course are occupied by the study of the chief non-metallic elements, and their simple compounds. Metallic salts, &c., are subsequently studied.

Fee, including the cost of materials and apparatus, for the Course, £4 4s.; Perpetual, £7 7s.

II. Senior Course.

This Course consists of Twenty Lessons, of two hours each, on Mondays and Saturdays, from 10 to 12, commencing in the first week in May.

The First Half of the Course includes tests for fixed and volatile organic acids, nitrogenised acids, sugars, glycerine, alkaloids, &c.

The Second Half of the Course includes tests for mineral poisons in organic mixtures; also tests for organic bodies, such as the alkaloids, when mixed with other organic substances.

Volumetric methods of the quantitative analysis of sugar and urea, chlorides, phosphates, hardness of water, alkalimetry, are practised.

Analysis of milk and of ashes of blood.

Fee, including cost of materials and apparatus, for the Course, £4 4s.; Perpetual, £7 7s.

C. SUMMER MATRICULATION COURSE.

Professor Williamson, F.R.S., assisted by Charles Graham, D.Sc.

This Course includes those parts of Chemistry which

are required for the Matriculation Examination of the University of London.

The Course consists of about Twenty Lessons in Practical Chemistry, and of an equal number of Oral Lessons. The Practical Lessons include the preparation of the common gases and acids, &c., and the study of their characteristic properties in relation to the elementary laws of combination.

The other Lessons are chiefly devoted to those parts of the subject which require fuller oral explanation than is given in the Practical Lessons. They include numerous exercises and questions, to which answers in writing are given by the Students. These Lessons will begin on Tuesday, April 8th, 1873, at 11 a.m.

The Class will meet on Tuesdays, Wednesdays, Thursdays, and Fridays, from 11 to 12; and some other meetings will be announced when the Class has assembled.

Fee, including cost of materials and apparatus, £4 4s.

ROYAL SCHOOL OF MINES AND COLLEGE OF CHEMISTRY.

The Lords of the Committee of Council on Education having decided to transfer the instruction in Physics, Chemistry, and Natural History from the Royal School of Mines, in Jermyn Street, and the College of Chemistry, in Oxford Street, to the New Buildings, in Exhibition Road, South Kensington, the Courses of Lectures and Practical Laboratory Instruction will in future be given at South Kensington.

Professor of Chemistry.—Dr. E. Frankland, F.R.S.

The instruction in Chemical Science embraces:—

(1). A Course of Lectures on Experimental Chemistry, with special reference to the applications of Chemistry in the Arts and Manufactures.

(2). A systematic Laboratory Course for the Practice of Chemical Analysis.

(3). An advanced Laboratory Course for technical applications of Chemical Analysis and for Chemical Research.

Chemical Lectures.—The Course consists of Forty Lectures on Mineral Chemistry and Thirty Lectures on Organic Chemistry.

Chemical Laboratories.—The Laboratories for instruction in chemical manipulation, in qualitative and quantitative analysis, the technical application of analysis, and in the method of performing chemical researches, are under the direction of Dr. Frankland, and will be opened on Monday, the 1st of October, 1872. The Laboratories at South Kensington Museum are now used for the instruction of the pupils of the Royal School of Mines.

There are three terms in the collegiate year, of three months each, commencing in the first week of October, January, and April, respectively. The Laboratory hours are from 10 a.m. to 5 p.m., with the exception of Saturdays, when the Laboratory closes at 2 o'clock.

Each Laboratory Student works independently, there being no classes. All operations are superintended by the Professor and his assistants. A table with drawers, cupboards, and shelves is appropriated to every pupil. The Institution supplies gas, fuel, and reagents. The larger and more expensive instruments of the Laboratory, such as air-pumps, thermometers, barometers, condensers, &c., may be used by the students, who are responsible for their safety. The students have to provide themselves only with the apparatus specified in the Laboratory regulations. More advanced students engaged in private researches have to supply themselves with such materials as are not included amongst the ordinary reagents of the Laboratory.

The charge for instruction in the Chemical Laboratory is £12 for three months, £9 for two months, and £5 for one month. This charge does not include the fees for attending the Lectures.

Professor of Metallurgy.—Dr. Percy, F.R.S.

The course of instruction in Metallurgy consists of Lectures and Laboratory Practice, especially in Assaying.

The object of the Lectures is the communication of such instruction as the student may be able to apply to the greatest practical advantage when he may be subsequently engaged in conducting any metallurgical process.

Metallurgical Laboratory.—This Laboratory is conducted by Mr. R. Smith, under the direction of Dr. Percy, and is devoted to practical instruction in Metallurgy, especially in Assaying. The nature of this instruction will be adapted to the special requirements of the student. It comprises:—Assaying in all its branches, especially of the more important metals, such as iron, copper, lead, tin, alloys of silver and gold, &c.; and the examination of ores and metallurgical products.

The ability of the student to make trustworthy assays is in every case thoroughly tested; and no certificate of competency is given to a student who has not furnished satisfactory proof that he is able to obtain accurate results.

There are three terms in the collegiate year, of three months each. The Laboratory hours are from 10 to 4 during November, December, January, and February; and from 10 to 5 during the other months, with the exception of Saturdays, when the Laboratory is closed.

The charge for instruction in the Metallurgical Laboratory is £15 for three months, £12 for two months, and £7 for one month.

Lectures to Working Men.—Short Courses of Lectures at suitable periods of the year are given in the evening to Working Men. These courses are systematic, and arranged so as to illustrate, within a period of two years, the principal subjects taught at the Institution. Those for the ensuing Session include Natural History, Geology, and Mineralogy.

KING'S COLLEGE.

Professor of Chemistry and Practical Chemistry.—C. L. Bixham, F.C.S.

Demonstrator.—W. N. Hartley, F.C.S.

Assistant ditto.—J. M. Thompson, F.C.S.

The Session commences on the 1st of October. Students of the first and second years are admitted to the Course of Theoretical and Applied Chemistry. The Course commences with a view of the forces which concur to the production of Chemical Phenomena, after which the laws of Chemical Attraction are discussed, and the Non-Metallic Elements and their principal compounds are described.

The metals and their principal compounds are next examined, care being taken to point out the applications of the Science to the Arts, and the processes of the different Manufactures of Metallurgy, and of Domestic Economy, are explained and illustrated.

Examinations of the Class, both *viva voce* and by written papers, are held at intervals during the Course, at the usual Lecture hour.

Third Year.—Students who have completed six Terms in this Department are admitted to a course of Practical Chemistry, consisting of Twelve Demonstrations in each term; and they go through a course of Manipulation in the most important operations of Chemistry, including the first steps of Analysis.

Any Student of this Department may be admitted to this Class at any period of his study, on payment of an extra fee.

Analytical and Experimental Chemistry.—Besides the Course of Chemical Lectures and the Summer Class of Practical Chemistry, provision is made for those Students who wish to become more minutely acquainted with the practical details of the Science. By means of this Class each Student is enabled to familiarise himself with the methods of analysis and research. After passing through a preliminary course of analytical operations, each Student devotes himself to such portions of the science as are most interesting to himself, or most likely to be practically useful to him. The Daniel Scholarship of £20, tenable for two years, is given every alternate year for original research in the Laboratory.

The Fees for admission to the Laboratory Class, exclusive of materials, are, for one month, £4 4s.; for three months, £10 10s.; for six months, £18 18s., &c.

EVENING CLASSES.

Classes for Evening Instruction are held at King's College from October to March, and during April, May, and June.

The Classes include one for the Elements of Chemistry and one for Practical Chemistry.

The fee for the former is £1 11s. 6d.; for the latter, £2 2s. The classes meet twice a week.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.

17, BLOOMSBURY SQUARE, W.C.

School of Pharmacy. The Session commences on October 1st, and extends to the end of July.

LECTURES ON CHEMISTRY AND PHARMACY, BY DR. REDWOOD.

These Lectures will be delivered on Monday, Tuesday, and Wednesday mornings, at 9 o'clock.

Part 1.—Physics in relation to Chemistry and Pharmacy.

" 2.—Chemistry of Inorganic Bodies.

" 3.—Chemistry of Organic Bodies.

Also Lectures on Botany and Materia Medica, by Professor Bentley. The first and second parts of this course, extending over the winter months, will be delivered at 17, Bloomsbury Square, on Friday and Saturday mornings, at 9 a.m. The third part of the course, on Systematic Botany, will be delivered at the Royal Botanic Gardens, Regent's Park, at 8 a.m.

Fees.—For registered apprentices and Associates of the Society, for either of the above courses, £1 1s.; for either part separately, 10s. 6d. For those not connected with the Society, £2 2s. for either of the above courses; £1 1s. for either part separately. Students have free admission to the Library and Museum.

Laboratory.—The suite of Laboratories for Practical Instruction in General and Pharmaceutical Chemistry will be opened on October 1st, under the direction of Professor Attfield, Ph.D. Fee for the entire Session of ten months, Twenty-five Guineas. The Laboratories are open from 9.30 a.m. till 5 p.m. Students can enter at any period during the Session.

Two Scholarships (the Jacob Bell Memorial Scholarship) of Thirty Pounds a year each, are open to competition annually in July.

The Board of Examiners meet monthly, and are required by the Pharmacy Act to examine "all candidates who may present themselves for examination in their knowledge of the Latin Language, in Botany, in Materia Medica, in Pharmaceutical and General Chemistry, and to grant Certificates of Competency."

CITY OF LONDON COLLEGE, LEADENHALL STREET, E.C.

The Annual Courses consist of three terms, each averaging ten Experimental Lectures. Fee, 5s. per term.

Subjects:—Junior Class, Chemistry—First year, Non-Metals; second year, Metals and (time permitting) Elements of Organic Chemistry. Senior Class, 7 to 8 p.m., Practical Analysis.

BIRKBECK LITERARY AND SCIENTIFIC INSTITUTION.

EVENING CLASSES.

Inorganic Chemistry—Mr. G. Chaloner. Tuesday, 8 to 9. *Practical Chemistry and Analysis*—From 8 to 10, Saturday evenings.

ISLINGTON SCHOOL OF SCIENCE, WINDSOR STREET, ESSEX ROAD, N.

Evening Classes for Experimental Physics and Chemistry, with Laboratory practice on Wednesday and Friday evenings. Fee 5s. per course of Thirty Lessons. Teacher, Mr. J. Howard.

LADIES MEDICAL COLLEGE.

The Ladies' Medical College, established by the Female Medical Society in order to teach to educated women the theory and practice of Midwifery and the accessory branches of medicine.

President.—Lord Shaftesbury. *Hon. Sec.*—Dr. James Edmunds.

Elementary Chemistry.—Lecturer, Mr. J. A. R. Newlands.

Fee for two Sessions' attendance upon the Lectures on Midwifery, Anatomy, Physiology, Medical Science, and Hygiene, £10 10s. Fee for each of the extra Courses, one Session, £1 1s.; two Sessions, £1 11s. 6d.

Further details as to the objects and operations of the Society, and prospectuses of the College, may be obtained by letter to the Lady Secretary, 164, Great Portland Street, W.; or from the Hon. Sec., 4, Fitzroy Square, W.

ROYAL POLYTECHNIC INSTITUTION.

309, REGENT STREET, W.

Classes and Course of Study in Chemistry and Experimental Sciences, Steam, Electricity, Galvanism, Light, Heat, &c., under the direction of E. V. Gardner, F.E.S., M.S.A., Professor of Chemistry to the Institution.

The Chemical Laboratory is open Mornings and Evenings throughout the year. The Assay Laboratory with its complete range of furnaces will be at the convenience of Pupils who study Metallurgy.

ROYAL VETERINARY COLLEGE, CAMDEN TOWN.

Chemical Professor.—Mr. R. V. Tuson.

LECTURES AT LONDON MEDICAL SCHOOLS.

ST. BARTHOLOMEW'S HOSPITAL & MEDICAL COLLEGE.

WINTER SESSION.

Lecturer.—Dr. W. J. Russell, F.R.S. Monday, Wednesday, and Friday, at 10 a.m. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. W. J. Russell, F.R.S. Monday, Tuesday, and Friday, at 11 a.m. One course, £2 2s.

CHARING CROSS HOSPITAL AND COLLEGE.

WINTER SESSION.

Lecturer.—Mr. C. W. Heaton, F.C.S. Monday, Thursday, and Friday, at 11. One session, £5 5s.

The Laboratory is open daily.

SUMMER SESSION.

Practical Chemistry.—Mr. Heaton, F.C.S. Monday and Friday. One session £2 2s.

Special Evening Classes. Advanced Chemistry, Tuesday and Thursday, at 7 p.m. Fee, £2 2s. per month.

ST. GEORGE'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. H. M. Noad, F.R.S. Tuesday, Thursday, and Saturday, at 11.30. One course, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Dr. Noad, F.R.S., Monday, Wednesday, Thursday, Friday, at 10. One course, including the use of apparatus and materials, £4 4s.

GUY'S HOSPITAL.

WINTER SESSION.

Lecturers.—Dr. Debus, F.R.S., and Dr. Stevenson. Tuesday, Thursday, and Saturday, at 11. One course, £4 4s.

SUMMER SESSION.

Practical Chemistry.—Dr. Debus, F.R.S. Monday, Wednesday, and Friday, from 10 to 1. One course, £4 4s. Practical Instruction is also given in the Laboratory by Drs. Debus and Stevenson during the Winter Session.

The Course of Lectures on Experimental Philosophy (Heat, Electricity, Magnetism, and Electro-Magnetism) is given on Wednesdays at 12 noon by Mr. G. Farrer Rodwell, F.C.S.

LONDON HOSPITAL.

Lecturers on Chemistry.—Henry Letheby, M.B., and C. Meymott Tidy, M.B. Monday, Wednesday, and Friday, at 10.30 a.m.

Practical Chemistry.—Dr. Letheby, M.B. Monday, Tuesday, and Saturday, at 9 a.m.

ST. MARY'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. C. R. A. Wright, F.C.S. Monday, Tuesday, Thursday, and Friday, at 10.15. £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. C. R. A. Wright, F.C.S. Tuesday and Thursday, at 11.30 a.m.; and Saturday, at 9 a.m. One Session, £3 3s.

MIDDLESEX HOSPITAL.

WINTER SESSION.

Lecturer.—Mr. Heisch. Monday, Tuesday, Friday, and Saturday, at 11. One session, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Mr. Heisch. Monday, Wednesday, and Friday, at 11. One session, £3 3s.

ST. THOMAS'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. A. J. Bernays. Wednesday, Thursday, and Friday, at 9. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. A. J. Bernays. Tuesday and Thursday, 10 to 12; Friday, 11; Saturday, 10 to 1. One course, £3 3s.

WESTMINSTER HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. A. Dupré, F.C.S. Tuesday and Thursday, at 3 p.m.; Friday, at 3.30 p.m. One course, £5.

SUMMER SESSION.

Practical Chemistry.—Dr. A. Dupré, F.C.S. Tuesday and Thursday, at 10 a.m. One course, £2.

TEACHERS OF CHEMISTRY IN LONDON.

Mr. F. C. Braithwaite.—54, Kentish Town Road, N.W. Chemistry and Toxicology, Monday and Thursday; Latin, Tuesday and Friday; Botany and Materia Medica, Wednesday and Saturday. All the classes commence at 8 p.m. Laboratory and Botanic Garden open daily, except Saturdays.

Mr. E. V. Gardner, F.E.S.—Berners College of Chemistry, 44, Berners Street, W. The course of study in each instance is directed to the express want of the pupil, or according to choice. A course embraces thirty or thirty-five Lectures, of a practical character, of about one and a half hours' duration. The usual practice of a Laboratory can be obtained, with every convenience, under the immediate direction and guidance of Professor E. V. Gardner.

Mr. Henry Matthews, F.C.S.—Laboratory, 60, Gower Street, Bedford Square. Instruction in all branches of Practical Chemistry, particularly in its application to Medicine, Agriculture, and Commerce. Laboratory open daily, except Saturday, from 10 to 5; on Saturday, from 10 to 1.

Dr. John Muter, F.C.S.—Laboratory, 231 and 235, Kensington Road. Prepares for examination of Pharmaceutical Society. Lecture hours for Session 1872-3:—Chemistry (Elementary), 10 a.m.; Botany (Structural), 11 a.m.; Chemistry (Advanced), 2 p.m.; Botany (Systematic), 3 p.m.; Materia Medica, 4 p.m.; Pharmacy, 2 p.m.; Latin, 9 a.m. and 4 p.m.; Practical Chemistry, from 10 to 4 daily. Museum of Specimens open from 12 to 1, and 4 to 5 daily.

Mr. John Newlands, F.C.S.—Laboratory, 13, Knowle Road, Brixton, S.W. Gives practical instruction in Analysis, and prepares gentlemen for various public examinations.

Mr. A. Vacher.—20, Great Marlborough Street, Regent Street.

UNIVERSITY OF OXFORD.

Professor of Chemistry.—Dr. Odling, F.R.S.

Demonstrator.—E. Madan, M.A.

A commodious Laboratory is attached to the New Museum.

Scholarships of about the value of £75 are obtainable at Christ Church, Magdalen, and other Colleges, by competitive examination in Natural Science.

UNIVERSITY OF CAMBRIDGE.

Professor of Chemistry.—G. D. Liveing, M.A.

MICHAELMAS TERM.

Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Practical Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 1 p.m.

LENT TERM.

Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Practical Chemistry, on the same days, at 1 p.m.

EASTER TERM.

Special Departments of Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Practical Chemistry, on the same days, at 1 p.m.

The Chemical Laboratory of the University is open daily, from 10 a.m. till 6 p.m.; so that Students can work there at such times as may be convenient to them; and the Professor will attend to give instruction at the times above specified. The Demonstrator of Chemistry (Mr. Hicks) attends daily for the same purpose, alternately in the morning and afternoon.

PROVINCIAL SCHOOLS.

BIRMINGHAM.—MIDLAND INSTITUTE.

Lecturer on Chemistry.—Mr. C. J. Woodward, B.Sc. Tuesday and Thursday, at 8 p.m.

Practical Chemistry.—Mr. C. J. Woodward, B.Sc. Saturday, 3 to 6, and 6.30 to 9.30 p.m.

BIRMINGHAM.—QUEEN'S COLLEGE.

WINTER SESSION.

Professor of Chemistry.—Alfred Hill, M.D., Borough Analyst. Tuesday, Thursday, and Friday, at 12.

SUMMER SESSION.

Practical Chemistry.—Professor A. Anderson. Thursday and Friday, at 2 p.m.

BRISTOL.—BRISTOL MEDICAL SCHOOL.

WINTER SESSION.

Lecturer.—Mr. Thomas Coomber, F.C.S. Monday, Tuesday, Wednesday, and Thursday, at 8.15. One Course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Mr. T. Coomber, F.C.S. Daily, except Saturday, at 8 a.m. One Course, £3 3s.

ROYAL AGRICULTURAL COLLEGE,
CIRENCESTER.

CHEMICAL DEPARTMENT.

Professor.—A. H. Church, M.A. Oxon.

Assistant.—E. Kinch, F.C.S.

The Autumn Session commenced on the 14th of August; it divides on the 6th of October, and terminates about the 20th of December.

The Chemical Instruction comprises Three Courses of Lectures and Laboratory Practice:—

- (1). 32 Lectures on Inorganic Chemistry.
- (2). 32 Lectures on Organic Chemistry.
- (3). 24 Lectures on Agricultural Chemistry.
- (4). 32 Lessons on Chemical Manipulation.
- (5). 32 Lessons on Qualitative Analysis.
- (6). 32 (or more) Lessons on Quantitative Analysis.

Catechetical Lectures are also given, while analyses of manures, oil-cakes, minerals, soils, waters, &c., are daily performed in the College Laboratories, and Chemico-Agricultural researches undertaken by the more advanced Students, under the immediate direction of Professor Church.

The text-books used are Church's "Laboratory Guide," Roscoe's "Chemistry," and Church and Dyer's edition of "How Crops Grow."

LIVERPOOL ROYAL INFIRMARY SCHOOL OF
MEDICINE.

Lecturer on Chemistry and Toxicology.—Dr. J. Campbell Brown.

Course of 100 Lectures. Monday, Tuesday, Thursday, and Friday, at 10.15. £5 5s.

Technological and other non-Medical Students may take out any of the divisions separately—Fee, £1 1s., but no certificates will be given until the whole course has been attended.

Practical Chemistry.—It is expected that the new Laboratories will be open in November for the reception of Students, when those who desire to prosecute practical Chemistry, analysis, or original research, will be provided each with a separate working bench and cupboard, with tests, fuel, water, and gas. Fees, from £2 2s. to £10 10s. per quarter.

Summer Practical Chemistry Course. Fee £3 3s.

A Class for the Practical study of Organic Chemistry will be formed during either the Winter or Summer Session—Fee, £3 3s., including materials and apparatus.

Gentlemen who are not Students of the School are also admitted to the Laboratory and Lectures.

The Laboratory is open daily from 10 to 4 (except Saturday), for the study of Practical Chemistry, and for Analysis.

ANALYTICAL LABORATORY AND SCHOOL OF
TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by Mr. A. Norman Tate.

A limited number only of pupils received. Hours of attendance, 9.30 a.m. to 5 p.m. (Saturdays, 9.30 a.m. to 1 p.m.). Pupils may enter at any time and for any term.

Fees—Three months, £15 15s.; six months, £26 6s.; twelve months, £52 10s.

The Laboratory is also open from October to end of April two evenings per week for practical work.

Lectures one evening each week.

A separate working bench is provided for each Student, and he is also supplied with all ordinary chemicals, gas, fuel, and the more substantial portions of Laboratory apparatus, but must provide himself with test-tubes, beakers, and other apparatus of a fragile nature.

In addition to the ordinary chemical studies, the course of instruction will, as far as possible, comprise all such studies as may be required for the successful prosecution of the particular branch or branches of Applied Chemistry

in which the pupil is to engage; as, for example, in the case of one intended for manufacturing pursuits, he would study architectural and mechanical drawing, so far as is required for the preparation of plans, &c., of chemical apparatus and manufactories, the nature and use of building materials, and the scientific principles and practical rules involved in building and constructive operations, and other scientific and practical information required in the arrangement, construction, and management of chemical manufactories, and the application of Chemistry to industrial pursuits.

COLLEGE OF CHEMISTRY, LIVERPOOL.

Founder.—Dr. Muspratt, M.D., &c.

Principal.—Mr. Martin Murphy, F.C.S., Professor of Chemistry.

The Course of Instruction given in the College of Chemistry comprises the teaching of Chemistry as a science, and the general application of chemical knowledge; also the teaching of the principles of those branches of physics which are allied with chemistry, such as light, heat, electricity, &c.

Particular attention is devoted to instruction in the practice of systematic analytical operations, whereby students will be enabled to determine accurately the general and proximate constituents of substances, and so arrive at a knowledge of their nature and properties.

Instruction in the application of chemical data to medicine and agriculture, and to the chemical and metallurgical operations, comprising Technology, will be given, to qualify students for these avocations.

The students will invariably be controlled and directed in their study and work by the Principal and competent assistants. Ample laboratory accommodation is provided for students, and such general appliances as will facilitate their progress in acquiring a knowledge of the specialities taught in the college.

The student's laboratories are open throughout the year. Hours of attendance—From 10 a.m. to 5 p.m. daily.

Fees—10 guineas per quarter of 3 months, or 35 guineas per annum, payable in advance. Students provide all their own apparatus and books.

Medical and Pharmaceutical students are admitted for 1 hour per day. Fee for 3 months, £2 2s.

A Course of Lectures will be delivered to the students during the winter months. Evening Classes.

Certificates of attendance recognised by the University and Apothecaries' Hall of London, and Apothecaries' Hall of Ireland.

LEEDS SCHOOL OF MEDICINE.

WINTER SESSION.

Lecturer.—Mr. J. Chapman Wilson, F.C.S.

Daily, except Wednesday and Saturday, at 11 a.m. First session, £4 4s. Second Session, £3 3s.

SUMMER SESSION.

Practical Chemistry.—Mr. Wilson, F.C.S.

Mondays and Tuesdays, 9.30 to 11. Each course, £3 3s.

General Chemical Students.—The Laboratories are open daily, under the direction of Mr. Wilson, for the instruction of General Students in Chemical Manipulation, Technical Chemistry, and all branches of analysis; and also for the use of gentlemen wishing to pursue special chemical researches.

The fees, payable in advance to the Treasurer, are as follows:—For one month, £4 4s.; for two months, £7 7s.; for three months, £10 10s.; for four months, £13 13s.; for five months, £15 15s.; for six months, £17 17s.; for nine months, £21. Special fees will be charged to Students who do not wish to work every day in the week.

The Chemical Museum contains minerals, metallic ores and metals, rare chemical substances, and illustrations of the most important chemical manufactures in their different stages.

Curator.—Mr. Scattergood.

**LEEDS MECHANICS' INSTITUTION AND
LITERARY SOCIETY'S LABORATORY.**

Chemical Classes and Laboratory for Instruction in
Elementary, Practical, and Analytical Chemistry.

Lecturer.—Mr. George Ward, F.C.S., with Assistants.

HIGH HARROGATE COLLEGE, YORKSHIRE.

Professor of Chemistry.—Mr. W. G. Mason, F.C.S.,
Certificated Science Teacher.

MANCHESTER GRAMMAR SCHOOL.**CHEMICAL DEPARTMENT.**

Professor.—Francis Jones.

Instruction is given in Inorganic Chemistry, Organic
Chemistry, Metallurgy, and Analytical Chemistry. There
is a lecture-room and second laboratory, affording accom-
modation for seventy-two Students.

MANCHESTER ROYAL SCHOOL OF MEDICINE.

(INCORPORATED WITH OWEN'S COLLEGE).

Lecturer on Chemistry.—Mr. Daniel Stone.

The usual Course for the Medical Boards.

A Laboratory is connected with the School.

OWEN'S COLLEGE, MANCHESTER.

Chemistry.—Professor H. E. Roscoe, B.A., Ph.D.,
F.R.S., F.C.S.

Senior Assistant.—Mr. C. Schorlemmer, F.R.S.

Junior Assistant.—Mr. Henry A. Smith, F.C.S.

Junior Class.—Wednesday and Saturday, from 9.15 to
10.15 a.m.

Subject: Inorganic Chemistry, comprising the laws of
chemical combination, and a description of the properties
and mode of preparation of the non-metallic elementary
bodies and their most important compounds.

Senior Class.—Tuesday and Thursday, from 9.15 to
10.15 a.m.

Subjects: Inorganic and Organic Chemistry, including
the properties of the metals and their compounds, and the
composition and relations of the best defined groups of
organic bodies, and the laws regulating their formation.

Students are expected to answer the written exercises
and attend the *viva voce* examinations given in these
Classes.

Fee.—For each Class, £3 3s.; for both Classes, £5 5s.

A Recapitulatory Lecture, without additional Fee, will
be given on Friday at 9.15 a.m., which members of both
Classes will be required to attend.

Organic Chemistry (Extended Course).—Wednesday,
from 3 to 4 p.m., and Friday, from 4 to 5 p.m.

This Course, on the Chemistry of the Carbon Com-
pounds, in which the subject of Organic Chemistry will
be completely treated, will be given by Mr. C. Schorlemmer,
F.R.S.

Fee, £3 3s.

Extra Class.—Wednesday, from 4 to 5 p.m.

Subject: Technological Chemistry.

The Chemical Principles involved in the most important
Chemical Manufactures will be chiefly considered in this
Course.

Students attending this Class must be acquainted with
the principles of Chemical Science. *Fee,* £2 2s.

Analytical and Practical Chemistry.**LABORATORY COURSE.**

Professor.—Henry E. Roscoe, B.A., Ph.D., F.R.S.

Senior Assistant.—Mr. C. Schorlemmer, F.R.S.

The aim of this Course is to make the Student practically
acquainted with Chemical Science, to enable him to
conduct analysis and original research, and to fit him for
applying the Science to the higher branches of Art, Manu-
factures, and Agriculture. To accomplish this, an attend-
ance of not less than four days per week during three
whole sessions is as a rule necessary. It is very advisable
that each Laboratory Student should attend or should

have attended the Course of Lectures on Theoretical
Chemistry.

The College Laboratory will be open for Students daily
from 10.30 a.m. until 5 p.m., except Saturdays, when it
will be closed at 1.30. The Laboratory is closed from
1.15 until 2, for dinner.

The Laboratory is fitted with every convenience for the
prosecution of practical chemistry, all branches of quali-
tative and quantitative analysis, and original research.

Each Student is provided with a separate working table,
set of tests, fuel, water, and gas, free of expense; but he
is required to find his own apparatus, a few of the more
expensive reagents, and the chemicals required for his
experiments. Other apparatus or instruments of a more
expensive description may be obtained on loan from the
Laboratory Steward, subject to regulations to be prescribed
by the Professor.

Fees for the Session.—Students working six days per
week, £21; ditto, four days, £17 17s.; ditto, three days,
£13 13s.; ditto, two days, £9 9s.; ditto, one day, £5 5s.
Students entering the Laboratory Class at or after Christ-
mas, for not less than two days per week, will be charged
two-thirds of the fees for the whole session.

Special Fees for Shorter Periods.—For six months, six
days per week, £17 17s.; five months, ditto, £15 15s.;
four months, ditto, £13 13s.; three months, ditto,
£10 10s.; two months, ditto, £7 7s.; one month, ditto,
£4 4s.

Lectures on the methods of Qualitative and Quantitative
Analysis, intended to supplement the instruction in Prac-
tical Chemistry, will be given by Mr. C. Schorlemmer,
F.R.S., on Mondays, from 4 to 5 p.m.

First year's Laboratory Students are recommended to
attend and answer the written exercises and the *viva voce*
questions given in this Class. *Fee,* £1 11s. 6d.

Chemical Calculations.—In this Class, instruction and
special practice is given by Mr. C. Schorlemmer, F.R.S.,
on Wednesday, from 4 to 5 p.m., in the methods of
Chemical Calculations, serving as supplementary to the
Lecture and Laboratory Courses. *Fee,* £1 1s.

The Lectures on Chemistry in Owen's College are
recognised by the University of London for its Medical
Degrees, by the Royal College of Surgeons, and by the
Apothecaries' Hall.

EVENING CLASSES.**Chemistry.**

First Lecture Course.—(The Non-Metallic Elements).—
Professor Roscoe. Monday, from 8.30 to 9.35 p.m.

Second Lecture Course.—(The Metals).—Mr. Smith.
Friday, from 8.35 to 9.35 p.m.

Third Lecture Course.—(Organic Chemistry).—Mr.
Schorlemmer. Thursday, from 8.35 to 9.35 p.m.

Laboratory Courses.—Professor Roscoe, Mr. Schor-
lemmer, and Mr. Smith. Monday, from 6 to 8.30 p.m.

**COLLEGE OF PHYSICAL SCIENCE,
NEWCASTLE.**

(IN CONNECTION WITH THE UNIVERSITY OF DURHAM).

Professor of Chemistry.—A. Freire-Marreco, M.A.

Junior Division.—General Principles of Chemistry;
History of the non-metallic Elements.

History of the Metals and their more important com-
pounds; Principles of Qualitative Analysis, Monday,
Wednesday, and Friday at 11 a.m.

Senior Division.—Elements of Organic Chemistry,
Tuesdays, at 11 a.m. Applied Chemistry, Thursdays, at
11 a.m. *Fee* £5 5s.

Practical Chemistry.—The Laboratory is open from
10 a.m. to 1 p.m., and from 2 to 5 p.m., except on Satur-
day, when it closes at 1 p.m.

Laboratory Fees.—Students working six days per week,
five guineas per term. Students working alternate days,
three guineas per term. Students working one day per
week, one guinea per term.

Evening Classes.—Inorganic Chemistry, Mondays, at 6,
commencing November 4, 1872.

SHEFFIELD SCHOOL OF CHEMISTRY.

1 and 3, SURREY STREET, SHEFFIELD.

Mr. A. H. Allen, F.C.S., delivers a Course of Thirty Lectures on Inorganic Chemistry and Metallurgy. Day and Evening Classes for the practice of Analytical Chemistry and Assaying.

SHEFFIELD SCHOOL OF MEDICINE.

A Course of Forty-Five Lectures on Inorganic and Organic Chemistry will be delivered during the Winter Session, by A. H. Allen, F.C.S.

The Summer Course of Practical Chemistry is conducted by Mr. Allen.

SCOTLAND.

UNIVERSITY OF EDINBURGH.

Professor of Chemistry.—Dr. A. Crum Brown, F.R.S.

ROYAL COLLEGE OF PHYSICIANS AND SURGEONS, EDINBURGH.

Lecturer on Chemistry.—Dr. Stevenson Macadam, F.R.S.E.

The Courses of Instruction in Chemistry include its applications to Medicine, Agriculture, and, the Industrial Arts; and they qualify for the University of Edinburgh and other Universities, the Royal Colleges of Physicians and Surgeons, the Navy, Army, and Indian Medical Service, and the other Medical and Public Boards.

The Lectures on Chemistry are delivered daily during the five months of the Winter Session. The Lectures form a complete Course, and special Lectures on Technological Chemistry are given. Tutorial Class Examinations are held during the Session.

The Instructions in Analytical Chemistry are conducted in the Laboratories at Surgeons' Hall, which are now open daily, under the personal superintendence of Dr. Macadam, for the instruction of gentlemen in Chemical Analysis, and the prosecution of researches in Manipulative Chemistry.

The Prelections in Practical Chemistry are also conducted in the Laboratories at Surgeons' Hall. The subjects selected for Examination are those with which Medical Students are specially called upon to exhibit a practical acquaintance.

Fees.—Lecture, £3 5s. (University Graduation, £4 4s.) Practical Chemistry (University, &c.), £3 3s.; Analytical Chemistry, £2 per month, £5 for three months, or £10 for six months.

UNIVERSITY OF GLASGOW.

Professor of Chemistry and Practical Chemistry.—Dr. Thomas Anderson, F.R.S.E.

ANDERSONIAN UNIVERSITY, GLASGOW.

Professor of Scientific Chemistry.—Dr. T. E. Thorpe.

GLASGOW MECHANICS' INSTITUTION.

Professor of Chemistry and Practical Chemistry.—Dr. R. Carter Moffat.

GLASGOW VETERINARY COLLEGE.

Professor of Chemistry.—Dr. R. Carter Moffat.

SCHOOL OF CHEMISTRY,

42, BATH STREET, GLASGOW.

Dr. Wallace, Mr. Tatlock, and Dr. Clark.

Scientific course of Lectures on Inorganic and Organic Chemistry, by Dr. Clark. From 12 till 1 daily. Commencing Tuesday, November 5. Fee for the course, £2 2s.

Laboratory Instruction in Analytical and Practical Chemistry, from 10 till 4 daily, Saturdays excepted. Commencing Tuesday, November 5. Fee for Six months, exclusive of apparatus, £8 8s.

Private Pupils, number limited to Three, £26 5s., for six months.

Evening course of Laboratory Instruction in Analytical and Practical Chemistry. Tuesday and Thursday, from 7 p.m. till 9.30 p.m. Commencing November 5. Fee for one night per week, £1 1s. per quarter. Two nights per week, £2 2s. per quarter.

Evening course of Lectures on Chemistry, in connection with the Practical Class, by Mr. Tatlock. Every Friday, from 8 p.m. till 9 p.m. Commencing November 8. Fee for the six months' course, 5s.

Spring course of Practical Medical Chemistry, by Dr. Clark. Commencing Tuesday, January 8. Fee, £2 2s.

Summer course of Practical Medical Chemistry, by Dr. Clark. Commencing Tuesday, May 5. Fee, £2 2s.

IRELAND.

DUBLIN.—TRINITY COLLEGE.

Professor of Chemistry.—Dr. Apjohn, F.R.S.

ROYAL COLLEGE OF SURGEONS, DUBLIN.

Professor of Chemistry.—Dr. Barker.

QUEEN'S COLLEGE, BELFAST.

Professor of Chemistry.—Dr. Andrews, F.R.S., &c.

QUEEN'S COLLEGE, GALWAY.

Professor of Chemistry.—Dr. T. H. Rowney.

A Laboratory for Practical Instruction is attached to all the Queen's Colleges. The usual Practical Course for the Medical Boards is given in the summer.

ROYAL COLLEGE OF SCIENCE FOR IRELAND.

STEPHEN'S GREEN, DUBLIN.

This college supplies as far as practicable, a complete course of Instruction in Science, applicable to the Industrial Arts. The subjects of Instruction are:—Pure and Applied Mathematics, Descriptive Geometry, and Mechanical Drawing, Mechanism, Theoretical and Applied Chemistry, Chemical Analysis, Physics, Botany, Zoology, Geology, and Palæontology, Mineralogy, Mining, Machinery, Surveying, and Agriculture.

Professor of Theoretical Chemistry.—W. K. Sullivan, Ph.D., V.P.R.I.

Professor of Analytical and Applied Chemistry.—R. Galloway, F.C.S.

Assistant Chemist.—W. Plunkett, F.C.S.

A course of Lectures on Inorganic and Organic Chemistry is delivered by Dr. Sullivan three times a week during the Session. Fee for the entire course, £2.

A course of Lectures on Technological Chemistry is delivered by Mr. Galloway twice a week during the session. Fee for the course, £2.

The chemical and Metallurgical Laboratories, under the direction of Mr. Galloway, are open every week day during the session, except Saturday. Instruction is given in the different branches of Analytical Chemistry, including Assaying, and in the methods for performing Chemical research. Each student is taught, not in class, but separately and independently; and he is supplied with a separate working table, with reagents, fuel, water, gas, and the larger and more expensive apparatus. Fee, for the session of nine months, £12; or for three months, £5; or for one month, £2.

There are four Royal Scholarships, of the value of £50 each yearly, with free Education, including Laboratory Instruction, tenable for two years; two become vacant each year; they are given to students who have been a year in the College. There are also nine Exhibitions attached to the College, of the yearly value of £50 each, with free Education, including Laboratory Instruction, tenable for three years; three become vacant each year. These are awarded at the annual May Examinations of the Science and Art Department.

A Diploma of Associate of the College is granted at the end of the three years' Course.

The Session commences on Monday, October 7th.

ON NOCTILUCINE.

By Dr. T. L. PHIPSON, F.C.S.

I HAVE given the name of noctilucine to a peculiar organic substance, first alluded to in my paper in the *Comptes Rendus* for 1860 (2e semestre, p. 541), and again in my work on "Phosphorescence" (London, 1862, p. 103), as the substance which causes the production of light in phosphorescent fish. This remarkable compound, which might almost be termed the *organic phosphorus*, is also the cause of the production of light by the glowworm, and probably by all other phosphorescent animals; it appears to be formed in a variety of circumstances at the expense of dead animal and vegetable tissue, and even by certain living plants (*Euphorbia*, *Agaricus*, &c.). My observations at present relate only to noctilucine as produced in the animal world.

At the ordinary summer temperature noctilucine is a semi-fluid, almost liquid, substance containing nitrogen; it is white, and in its natural state contains a considerable amount of water; it has a slight odour, resembling that of caprylic acid; it is only slightly soluble in water, and is somewhat lighter than this liquid; it is insoluble in alcohol and ether, and is decomposed by acids and alkalis. Nitric acid easily dissolves and decomposes it; sulphuric acid, also, and potash evolves ammonia from it. In fermenting, in contact with water, it produces an odour of putrid cheese; as long as it is moist, it absorbs oxygen and evolves carbonic acid in the air. When left to itself it dries up, in the course of a few hours, to thin, shining, translucent films, quite devoid of structure, and resembling the *muscle* of the common garden snail.

When recently produced noctilucine is highly phosphorescent, and this production of light is owing to oxidation in contact with the air. It also shines for a little time in water, as long as there is air in the water; it is rather more brilliant in oxygen gas, and still more brilliant in a south-west wind, which I find usually contains much ozone. This production of light ceases as soon as the oxidation is completely accomplished; but as long as the smallest amount of air adheres to it, it will shine, even in carbonic acid, for a short time.

Noctilucine is secreted in phosphorescent animals by a special organ, just as bile is secreted by the liver, and appears to be used in producing light nearly as fast as it is formed. It is also produced in certain conditions of temperature and moisture, in dead animal matter of various descriptions (pork-flesh, beef, blood, fish, &c.) and occasionally in urine. Whatsoever its source, it shows the same kind of light, nearly monochromatic; the same spectrum, principally developed between the lines E and F; and, as far as I have examined them, the same chemical properties.

In an impure state, noctilucine can be obtained from the surface of various fish when highly phosphorescent, also from the glowworm, by pressing the luminous matter collected by the scalpel through porous filtering-paper. It is secreted in a pure form by the luminous centipede (*Scolopendra electrica*), and on the 15th of September, 1871, I procured some from this source. When a number of these *Scolopendra* are caused to run about a large glass capsule, they leave a certain amount of noctilucine upon the surface of it, sufficient to enable one to examine the principal properties of this curious substance.

The secretion of noctilucine in the higher phosphorescent animals, such as the glowworm and the firefly, is to a certain extent dependent upon the nervous system of these insects; hence they have the faculty,

apparently, of shutting off their light at will. In this case the secretion is stopped for the time; but a certain quantity of noctilucine exists in the eggs of the glowworm, which also shine for some time after they are deposited.

There appears to be a special organ for the secretion of noctilucine, even in the minute *Noctiluca miliaris* of the English Channel, and other lower types of phosphorescent animals; and even here, where we find scarcely any rudiments of a nervous system, the secretion of the luminous substance appears to depend greatly upon external circumstances.

DIDYMIUM IN BRITISH MINERALS.

By A. H. CHURCH, M.A., F.C.S.

DIDYMIUM was first discovered in a British mineral by Mr. C. Greville Williams, F.R.S., in the year 1865. This fact is recorded in the *CHEMICAL NEWS*, vol. xii., p. 183. The mineral containing this rare metal was described by me as "a new British mineral containing cerium." Analyses proved it to be a hydrated phosphate of the cerium metals, the latter, calculated as cerous oxide, constituting no less than 51.9 per cent of the mineral. Specimens of this mineral may be seen in the British Museum, Mineral Case No. 57. It is, however, very rare, and I hesitated to sacrifice the specimens which I possess in order to attempt a precise estimation of each of the cerium metals present. It occurred in a Cornish copper lode on quartz and killas. A concise description of the species will be found in Dana's "Mineralogy," p. 555, (5th Edition, 1868).

The above remarks were suggested by Mr. C. Horner's note on the presence of didymium in pyromorphite (*CHEMICAL NEWS*, vol. xxvi., p. —). The occurrence of cryptolite in certain British, as well as foreign specimens of apatite has been ascertained. Now as cryptolite is an anhydrous phosphate of the cerium metals, it may be considered that the discovery of this species in apatite is equivalent to the detection of didymium in that mineral. I must say I have failed to find even a trace of cryptolite in the true asparagus-stone, the beautiful greenish-yellow crystals of apatite, from Juniella, in Murcia, Spain.

Mr. Horner's discovery of didymium in pyromorphite will naturally lead to the search for the other cerium metals in that mineral.

Isopurpuric Acid and Salts as Dye Materials.—

According to the recent researches of Dr. E. Kopp, isopurpurate of potassa is best obtained by treating an intimate mixture of picric acid and cyanide of potassium, first with a small quantity of cold water, and after this mixture has been left standing for about half an hour, more water is added and the temperature raised to from 40° to 45°; after cooling, the mass is purified according to Hlasiwetz's process. The best mordants for isopurpurates on silk and wool are mercuric and lead salts; the hue of the colours produced differs from that of those produced from murexide under the same conditions, inasmuch as the isopurpurates yield a magnificent purple with a somewhat brownish orange-hue. The colour is fast as regards sunlight and sulphurous acid, both of which destroy murexide colours. While murexide-zinc yields a beautiful yellow, isopurpurate of zinc yields deep red, somewhat brownish, hues. Murexide colours do not stand acids and alkalis at all; these reagents render isopurpurate colours somewhat yellow. The alkaline isopurpurates are explosive salts, but the purpurates are not; many reagents decompose these salts entirely, giving rise to the formation of secondary compounds. Isopurpurate of potassa is more advantageously prepared by causing the cyanide of potassium to act upon the picrate of ammonia.

SUPPLEMENT
TO THE
CHEMICAL NEWS.

VOL. XXVI. No. 668.

THE STUDY OF CHEMISTRY.

CHEMISTRY may be studied as a means to an end, and as an end. The importance of chemistry to every kind of manufacture has become fully acknowledged as not only affording many improvements, but as a means of economy. But to the chemical manufacturer, as well as to the purely scientific chemist, the advanced study of chemistry is the end of their labours; yet in both instances the routine pursued by the students may be the same, the difference being one of degree of attainment. We say that the routine may be the same, for we cannot recognise the method of committing to memory some text-book as being at all worthy of the name of a course of scientific study. Such a method is perhaps suited to the debating society, where the casual employment of a hard name bears an indefinite effect, but is certainly not calculated to supply knowledge that either would satisfy a conscientious examiner or be of material worth. There is, then, left two methods of study, differing, as has been said, only in degree—(1) study by attendance in class on experimental lectures, with *viva voce* instruction; (2) study, either singly or collectively, in a laboratory under a practical chemist. These methods bear to each other a relation somewhat similar to that existing between clinical medicine as studied in the hospital and in practice, or between book-keeping learnt at school and pursued in the office. The first method may precede the second with advantage, but alone it will rarely lead to thorough comprehension of the science, because the student is so much dependent upon the reasoning of his Professor, that for practical work by himself he remains quite unprepared, unless the second method should have been to some, and even slight, extent supplementary. There are, too, so many points of detail that fix themselves indelibly in the memory during a course of laboratory work, to which hand and mind become alike accustomed, and which even the lapse of years will not obliterate. This view of chemical science, its consideration as a collection of experimentally-ascertained facts, is most essential to the student. A presently-received theory may in the course of years undergo such marked changes as to appear almost unrecognisable to those to whom the changes have passed unnoticed; but a fact—well, “a fact is a fact for ever”—and, once made, by experiment, the student’s own, is equally ever afterwards an inalienable property. It has unfortunately been a course too often adopted to ask, of students qualifying for science certificates, a merely theoretical knowledge of their subject. But several instances could be indicated where there is a growing tendency to test the knowledge of the candidate experimentally and practically. And that this tendency meets with encouragement, from the students themselves as well as from examiners, is evidenced by the transference of the principal source of our chemical instruction from the School of Mines and Oxford Street to larger lecture-rooms at South Kensington, as well as by the foundation of institutions such as

the College of Physical Science recently established at Birmingham. The student of to-day enjoys the further advantage of a course of chemical instruction—elementary it may be—during his school days, especially if he be intended to attempt an Oxford or Cambridge Local Examination, elementary examinations that are eminently practical in their nature. That the importance of early culture in scientific enquiry is becoming duly recognised is also evident from the impetus given to science studies at the somewhat exclusive Universities of Oxford and Cambridge. From the former seat of learning we have been accustomed to hear from the lips of the Waynflete Professor brilliant elucidations of the most intricate reasoning on chemical subjects, and it is not without pleasure that we note the acceptance of the chair by Dr. Odling, F.R.S., whose practical teaching at the Royal Institution has met with so much favour. At Cambridge, the election of a Science Tripos is an act of to-day. At the Universities of London, Dublin, Edinburgh, Glasgow, and others, the science classes were never so well attended and the candidates for scientific distinction so numerous. And it is interesting to notice that the attention bestowed upon chemistry is far above that given to any one other subject of scientific study, arising doubtless from the manner in which chemistry, owing to the numerous discoveries of the last decade, is fast becoming an integral part of other applied science. A knowledge of chemistry is now almost as essential to the engineer as to the chemist. In naval architecture, recent events have proved that the disregard of molecular action may be attended with awkward consequences; while the highest branches of chemical enquiry are brought in to aid in the improvement of the material itself of which our vessels are constructed. To enumerate the results of the application of chemistry to manufacture during the last century would be to record more brilliant triumphs than are to be found in the annals of Ancient Greece and Rome. Who would not endeavour to follow, however distantly, in the footsteps of such men as Faraday, Wollaston, and others of the day whose names are household words?

Turning from the higher branches, we have the classes for instruction in science under the direction of the Committee of Council of Education, in which the artisan may gain an acquaintance with the rudiments of chemistry. The teaching of these classes has always been practical, and its benefit, although felt but only indirectly, is none the more real; and that it is fully appreciated is shown by the eagerness with which the testimonials of the Department are sought.

Medical and toxicological chemistry, a branch spreading widely from the parent tree, is, from the increased delicacy of means of determination, now able to prepare or detect the most subtle medicines and poisons with an accuracy formerly unthought of. Chemistry, in short, must now rank as one of the exact sciences, as it is one of the most important; and without doubt it has arrived at its present stage of advancement by means of a careful discrimination and a close attention to fact.

In placing before our Students this number of the CHEMICAL NEWS, specially devoted to them, and in recommending to their notice the curricula of the several schools, we admonish them to a practical, or rather, should we say, experimental, course of study in the science they have chosen.

THE SEWAGE COMMITTEE OF THE BRITISH ASSOCIATION.

PRACTICALLY the Gun-Cotton Committee of the British Association was Professor Abel, and now practically the Sewage Committee is Mr. Hope. That Mr. Hope's sewage-farm at Romford is skilfully and advantageously worked, and more especially shows the merits of sewage irrigation, strikingly set forth and contrasted with other ways of disposing of sewage, may be, and we believe is, essentially true—but why this should be, as it appears to be, the sole accepted mission of the Committee of the British Association on the Treatment and Utilisation of Sewage, is not so clear.

It will possibly be within the knowledge of some of our readers that in the year 1870 this Committee collected £1530 from various towns in the United Kingdom, and so became possessed of a sum of money equal to the collective amount which the British Association spends annually upon all its committees.

At the recent meeting of the Association in Brighton, the Sewage Committee announced that it had expended all its money and applied to be re-appointed, and for a grant of £100 from the general fund of the Association. Furthermore, there was an intimation that a repetition is contemplated of its appeal to the towns for pecuniary assistance.

Under these circumstances, the history and doings of this Committee are of public interest; and, indeed, one of the leading London papers has publicly remonstrated with the leader of Her Majesty's Opposition in the House of Commons, for not taking part in "the great sewage debate" in Section B.

Here we may observe, in passing, that curiously enough the very occurrence of this great sewage debate appears to be contrary to the rules, or at any rate to the ordinary course of procedure, in the Sections, of the British Association, and that we are indebted for it to the public spirit and sense of right of the President, Dr. Gladstone, who, resisting official pressure, put the question to the Chemical Section on the Tuesday, whether or not there should be a sewage debate on the Wednesday. The question was answered unanimously in the affirmative by the members of the Section, and accordingly the debate came off.

The Sewage Committee of the British Association began very humbly at the Norwich meeting in the year 1868 with a grant of £10. In the following year it was re-appointed in Exeter, and received a grant of £50; and between that meeting and the meeting in the summer of 1870, as already described, it executed the feat of collecting £1530 from the towns.

The Committee appointed in Exeter, in 1869, consisted of Mr. Grantham, Mr. Denton, Mr. Harrison, Mr. Hope, Dr. Paul, and Professor Wanklyn; and was constituted "without power to add to its number." It nevertheless added Professor Williamson and some others, and appealed to the towns for funds. A question then arose with the Committee as to the application of the money. One party maintained that members of the Committee were bound to work for the Committee, and that the payment of personal expenses, while actually thus engaged, was a legitimate application of the funds. The other party maintained that the members were not bound to work, and that the receipt of personal expenses would not be sanctioned by the British Association. The dispute related mainly to the chemical work, and was between the two chemists who had been appointed at the Exeter meeting, and who wished to work, and the other chemist subsequently appended. The dispute grew, and was complicated by the further question whether a committee, without explicitly getting power to add to its members, could exercise such a power? and the Council of the Association was appealed to, and decided that all Committees of the Association have power to add to their

number, whether they are constituted "with power" or not.

In this way Professor Williamson, the chemist appended by the Committee, triumphed over Dr. Paul and Professor Wanklyn, the chemists appointed by the Exeter meeting of the Association. At Dr. Williamson's suggestion, and in opposition to the protest of Messrs. Paul and Wanklyn, a former assistant of his, viz., Dr. Russell, at that time of St. Mary's Hospital, and at present of St. Bartholomew's, was nominated chemist to the Committee.

Messrs. Paul and Wanklyn thereupon issued a circular to the subscribing towns respecting this transaction, stating that the question put to the subscribing towns was whether the main work of the Committee was to be done by its members at an unremunerative rate, or by friends of the Committeemen at a remunerative rate. Many towns returned answers favourable to Messrs. Paul and Wanklyn, but not having sufficient support within the Committee, they protested, and left the field to Dr. Williamson, who, in conjunction with his nominee, Dr. Russell, is responsible for the chemical work of the Committee.

Of the six members of the Sewage Committee appointed in 1869 by the British Association in Exeter, only Mr. Grantham, who was chairman, and Mr. Hope, who is proprietor of a sewage-farm on which the Committee make experiments, remain in a state of activity. Of the other four members three have withdrawn, and one, viz., Mr. Harrison, has become passive. Tracing the history of the Committee, we find that it reported and was re-appointed in Liverpool in 1870; that it reported and was re-appointed in Edinburgh in 1871; and again in Brighton in 1872. Confining ourselves to the events in Brighton, we have to record that attention was called to the circumstance of this Committee applying to the sectional Committee of the Mechanical Section of the British Association for recommendation to be re-elected, before its report had been read, in the Section; that after the reading of the report discussion was forbidden, as being contrary to the rule of the Association; and that efforts were made to prevent the discussion of it in the Chemical Section, but that they were frustrated by the determination of the President and the action of the Section. When the debate came off, considerable distrust of the accuracy of the work done was expressed in some quarters. The report itself was strongly in favour of irrigation.—*Mechanic's Magazine*.

CHLOROPHYLL AND ITS RELATION TO LIGHT.*

By Professor LOMMEL.

It is well known that green plants decompose the carbonic acid in the atmosphere, retaining the carbon and giving back the oxygen. This assimilation of carbon takes place in the chlorophyll cells under the influence of light. The chlorophyll will not effect it without light of fitting quality and intensity; the light will not effect it where there is no chlorophyll. Hence it is important to study the relation of chlorophyll to light.

Two optical properties of chlorophyll may here be considered: its *absorption* of light, and its *fluorescence*.

To study the former, an alcohol or ether solution of chlorophyll is placed between the source of light and the slit of a spectroscope. The position of the absorption-bands may be compared with that of Fraunhofer's lines.

Where there is much thickness of liquid, or the solution is a strongly-concentrated one, the extreme red only appears; the rest is absorbed. On further dilution, green, yellow, and orange successively appear. A solution from fresh leaves gives a spectrum with the following characteristics:—Immediately after B, in the middle of the red, is a dark band extending a little beyond C; this

* Abstract of a Paper in *Poggendorff's Annalen*.

may be numbered I. Another weaker absorption-band appears in the orange-yellow, half way between C and D (II.), a third (III.) in the greenish yellow after D, a fourth (IV.) in the green immediately before E. The order now given is also that of their intensity. The rest of the spectrum from before F is absorbed. Only, in certain cases, a slight weakening of the absorption appears about G, which may thus be regarded as the dividing line between two very broad absorption-bands, numbered by Hagenbach VI. and VII. Hagenbach's line No. V. is one which only appears from a solution that has been standing some time; it is situated between B and F.

Next, as to fluorescence. When a solution of green leaves is placed in sunlight or candlelight, *e.g.*, it shines with a peculiar dark red light, which may be intensified if the incident light is concentrated by a lens, and then the liquid appears as if self-luminous. To ascertain which part of the incident light caused this appearance, a solar spectrum was cast on the surface of the solution. The red gleam appeared throughout the extent of the spectrum from a little before B to the ultra violet part, and with varying intensity. Seven bright bands were discernible, and each of these corresponded, in position and intensity, to a dark band of the seven perceived in the former absorption spectrum. (Or, if No. V. be discarded, which only appeared in the modified solution, then VI. and VII. became one.)

The fluorescent spectrum was then, by means of a cylindrical lens, contracted to a narrow band, and this was examined through a prism with the refracting surface parallel to the spectral band. The spectrum of this "diverted" fluorescent light contained only red rays, with a refrangibility corresponding to that of the rays between B and C in the solar spectrum.

We thus learn that only the rays of light which are liable to absorption produce fluorescence in the solution, and the fluorescence is proportional to this liability. Further, the fluorescence may be called forth by any homogeneous ray.

The connection between fluorescence and absorption may be here looked at a little more closely.

Euler established the principle that a substance absorbs all those rays of light with whose rate of vibrations the vibrations of its smallest particle can agree.

Each molecule of a substance, according to its chemical structure, has certain determinate rates of vibration. If it is struck by a wave whose period agrees with one of those proper to itself, it is set in motion, or has its motion strengthened, if it has already been vibrating. The wave gives up its energy, partly or wholly, to the molecule, goes through the substance weakened, or does not go through at all, *i.e.*, it is absorbed.

Other vibrations, not agreeing with those of which the molecule is capable, pass through. We have an analogous case in Resonance. It must further be pointed out, however, that wave motion may also be absorbed when the molecule's rate of vibration is only half as great, or twice as great, as that in the wave; or, to use acoustical language, when it is an *octave* lower, or an *octave* higher, than the impinging wave. This may be called the principle of *indirect*, and the former that of *direct*, absorption. Such indirect absorption, as may be supposed, commonly exceeds the direct in energy, and absorption through the lower octave is generally greater than that through the higher.

Once more, a molecule is commonly capable, not of one kind of vibration only, but of various, which are more or less readily excited; and in whatever way the molecule is put into vibration, all those vibrations will take place simultaneously which are proper to it. In acoustics, there is the analogous case of *overtone*, or overtones.

We have, then, the principle, that when a molecule, through direct or indirect absorption, is put in vibratory motion, it vibrates not only in the vibration-period of the absorbed wave, but the other vibrations proper to the molecule are conjoined with this.

Thus we may see how the chlorophyll molecule acts. We perceive that it is capable of vibrating in the vibration-period of the rays between B and C and the next octave below, while it vibrates only in the next lower octave of the more refrangible rays. In the former case there is direct and indirect absorption, in the latter only indirect. In those parts of the spectrum with whose vibration-period, or the next lower octave, the chlorophyll molecule readily agrees, there are dark absorption-bands. The dark bands in blue and violet arise from the molecule vibrating with half the vibration-period of the blue and violet rays; while, in the case of the bands between B and C, the molecule vibrates not only with half the vibration-period of the red rays, but also with the same vibration-period.

The molecule, set in vibration, itself sends out rays, one portion of which have rates of vibration half as great as those of the rays from B to the violet end of the spectrum, and another, rates equal to those of the rays between B and C. The former are not perceived, being in the ultra-red; the latter are perceived as red fluorescent light.

Hence may be understood how every absorbed ray, whatever its colour, produces only red fluorescent light; how the bright fluorescence bands correspond to the dark absorption-bands; and how the extreme red before B, which is not absorbed, also excites no fluorescence.

This theory is in opposition to that of Stokes, according to which every ray giving rise to fluorescence calls forth only such rays as have a rate of vibration inferior to its own. By the use of an alcohol solution of rose of Magdala, I have also been able to obtain yellow and greenish yellow rays from red rays. (An additional experiment confirmatory of the theory is here described.)

Chlorophyll in the leaf acts much in the same way, with reference to light, as chlorophyll in solution. It was found, however, that, on causing the light to pass through a single leaf, the absorption-bands II., III., and IV. (which appeared in the solution) were not present. There was strong absorption only in the red between B and C, and in the violet; chlorophyll in the solid state, moreover, gives no fluorescence.

If, now, we seek to answer the question, What kind of rays are most productive of the assimilation of carbon in the plant? it is clear, first of all, that only an absorbed ray can act chemically. The chemical action in the cell arises from the energy communicated on absorption of the ray. The most chemically-efficient ray must therefore be sought among those that are most easily and perfectly absorbed.

But it is also necessary to know the "mechanical intensity" of the ray. A ray that is not absorbed will not produce chemical action; and a ray which is perfectly absorbed produces but a small effect if its mechanical intensity is small.

Have we the means of measuring the mechanical intensity of sun-rays?

The luminosity of the ray, or its "physiological intensity," furnishes evidently no criterion; nor does the action of rays on salts of silver or explosive gas supply a proper criterion. Every ray may act chemically which is absorbed. Different substances absorb different rays; in one the red, in another the violet, produces chemical action. That the violet and ultra-violet rays act chemically, *e.g.*, on salts of silver, is no reason for distinguishing these as "chemical rays." The curve of so-called chemical intensity in the spectrum only indicates the relation of the rays to particular reagents.

We have, however, in lamp-black a substance with the aid of which the mechanical intensity of all rays may be estimated, since all kinds of rays are perfectly absorbed by it and their energy transformed into heat. By passing a thermopile, the end of which has been covered with lamp-black, along the solar spectrum, the mechanical intensity of the various rays can be measured. By this means it is ascertained that, in a spectrum formed through a rock-

salt prism, the heating power is at its maximum in the ultra-red : from there it decreases towards the violet end, where it is smallest.

For the assimilating action in plants, the most efficient rays are those which are most strongly absorbed by the chlorophyll, and at the same time have a high mechanical intensity or heating power. They are the red rays between B and C.

The blue and violet rays, though largely absorbed, are little operative, their mechanical intensity being small. The extreme red rays produce no chemical action, because they are not absorbed. The yellow rays, notwithstanding considerable mechanical intensity, are little operative, because they are very little absorbed. The same holds good for the orange and the green.

The experiments I have hitherto made on the assimilation power of plants in light of different colours have confirmed the foregoing statements, or at least have presented nothing in contradiction of them. These experiments can only with difficulty be compared with each other, as the mechanical intensity of the incident rays was left out of account. The thermo-multiplier must in future be regarded as a necessary instrument in any laboratory for the study of plant physiology.

Dr. Lommel concludes with a short account of some experiments by Professor Sachs, of Würtemberg, in which eaves were put in a glass tube containing a known amount of carbonic acid; this was enclosed in a glass receiver, which held a coloured solution, and thus exposed to sunlight. The decomposition of the carbonic acid was afterwards measured. In this way it was found that, with a chromate of potassium solution, which absorbs the more refrangible part of the spectrum and allows the rest to pass, including the efficient red rays between B and C, a marked decomposition took place; with a solution of ammoniac copper, on the other hand, which allows only the blue and violet to pass, and absorbs the remaining part of the spectrum, the action was very little. A chlorophyll solution, for the same reason, gave very little action, the red rays between B and C being absorbed.

ON SOME NEW METHODS OF ANALYSING ETHERS.*

By J. ALFRED WANKLYN.

Two methods were proposed. The first consisted in saponifying the ether, and then measuring or weighing the alcohol formed during that operation. It is well known that the acid obtained on saponifying an ether may be titrated, and Professor Wanklyn showed some years ago that this determination may be made with a high degree of accuracy. The determination of the alcohol set free is, as will be observed, complementary to the determination of the acid.

In carrying out the new process, the following is the method of operation :—

A portion of the ether to be analysed is accurately weighed. 5 or 10 grms. may be conveniently taken. This is then sealed up with excess of aqueous solution of baryta, digested in the water-bath until the decomposition of the ether is complete. The tube is then opened, the contents diluted with water and submitted to distillation—the distillate, consisting of weak alcohol is weighed, and its sp. gr. is taken.

Instead of baryta, it is possible to employ caustic potash in solution in alcohol; but in the latter case it is necessary to use a known quantity of alcohol, which must afterwards be taken into account, being subtracted from the total amount of alcohol which distils over at the termination of the experiment.

The author expects that these estimations of the alcohol

* Abstract of a paper read before the British Association, Brighton Meeting, Section B.

evolved on saponification of ethers will prove to be very precise, and that indeed they should be among the most accurate determinations in organic chemistry. That the saponification of an ether can be effected with precision is quite certain. That weak alcohol can be distilled off excess of alkali with precision, the authors experiments on ethylate of soda have proved.

The second process of analysis proposed by Professor Wanklyn is to decompose the ethers by means of excess of strong hydriodic acid. This is especially designed for the fats which are salts of glycerine, and which ought to yield Erlenmeyer's iodide of isopropyl. By this means it is hoped that the percentage of glycerine derivable from any given fat may be estimated. There is a little uncertainty how the acid evolved from a fat will behave towards excess of hydriodic acid, or towards iodine, phosphorus, and water, and this point awaits experiment. The author proposes to examine butter by this process.

NOTICES OF BOOKS.

The Hygiene of Air and Water. Being a popular account of the Effects of the Impurities of Air and Water, their Detection, and the Modes of Remedying them. By WILLIAM PROCTER, M.D., F.C.S. London: R. Hardwicke. 1872.

THIS work gives a clear and simple statement of the injurious effects produced on health by impure air and water. It treats of the various means of detecting the impurities, and gives many useful tests in common language; we quote one of practical value:—"A weak solution is made of permanganate of potash, or Condy's (crimson) fluid, which is a similar solution, is diluted—either of them is the test solution. Take half a pint or more of the water to be examined, previously acidified by the addition of a few drops of hydrochloric acid, or about 12 drops of sulphuric acid (oil of vitriol) diluted with 5 parts of water; add the test solution, drop by drop, whilst stirring, until a faint pink tinge is perceptible. Every 15 minutes the water is to be looked at, and as the colour disappears, a few drops more of the test solution cautiously added, and this is to be continued until the colour remains permanent for half an hour. All the organic matter is then destroyed (oxidised), and the quantity of solution required to effect this gives a rough estimate of the matter originally in the water. The change of colour is better observed by placing the vessel upon a sheet of white paper before a window, and looking down at the paper through the liquid. This is a simple process, and it is within the power of all to ascertain the fitness of our water supply for dietetic purposes." The remainder of the work is equally simple, and as highly valuable in character.

TO CORRESPONDENTS.

. We cordially thank those gentlemen who so kindly acceded to our request, in sending us the necessary information respecting the Chemical and Medical Schools for our Students' Number.

J. Spiller writes to complain of the adoption, without acknowledgment, in M. Emile Kopp's paper on "Processes for Distinguishing and Separating Silk, Wool, and Vegetable Fibres in Mixed Tissues," published in our issue of the 30th of August, of the specific test for silk which he brought before the Liverpool Meeting of the British Association in 1870.

THE CHEMICAL NEWS.

Vol. XXVI. No. 669.

OFFICERS OF HEALTH.

THE onerous duties attached to the public position of a Medical Officer of Health render it necessary to consider whether our present system is the best that could be devised. Under the Public Health Act of this year it has been enacted that, for the approval of one of Her Majesty's Principal Secretaries of State, is to be substituted the direction of the Local Government Board in the appointment and removal of analysts. Whether this new *régime* will bring and maintain competent men in the several official positions remains to be seen; but it appears to greatly interfere with the independence of the Officer, who may be exposed to much annoyance and opposition. No one will dispute that the independence of the Officer is a point of the highest importance, and that it should be secured at any cost to the administration. The Officer should be adequately salaried, in order that he may devote his entire energy to the duties of his office; and consequently his appointment should have the permanency necessary to ensure that there may be no fear as to the future.

We have next to consider the qualifications required for the proper discharge of the duties of the office. Not only is it required that the Officer should possess high medical testimonials, he must also be an accurate analyst in the most difficult branches of chemical science. He must be well versed in the detection of poisonous agents and impurities in food, in the water supplied to the community; while, besides his ordinary medical education, the candidate should be expected to have given special attention to the laws of hygiene and of contagious diseases. The question arises, whether one man can be considered to attain to an adequate knowledge of these various branches of science. It is generally held that chemistry alone is the study of a lifetime, while "young" doctors are rarely regarded with a favourable eye. We have, then, ample reason for an innovation, to consist in the separation of the offices of Medical Officer and Analyst. Were these offices distinct, yet worked in partnership, there would even then be sufficient work for each officer. To any one in the least conversant with chemical processes, and the length of time and repetition necessary to an accurate determination, it must appear ridiculous to suppose that the multifarious duties of a Medical Officer of Health can be undertaken by one person with any chance of accuracy in detail. Everyone will therefore be in favour of the movement now set on foot in the parish of St. George's, Hanover Square, where it is proposed to divide the duties of the Medical Officer of Health between two, a medical man and a chemist. The chemist who offers himself is Dr. Dupré, Lecturer on Chemistry at Westminster Hospital; while the medical profession is represented by Dr. R. J. Lee, M.A., M.D. Cantab, Lecturer on Forensic Medicine at the Westminster Hospital. It is to be hoped that these gentlemen will meet with success in their candida-

ture, not only on account of their eminence in their professions, but for the principle which their joint appeal to the parishioners of St. George's involves. The present system, though admirably carried out by some men who have sacrificed themselves to their office, to be placed in some instances under the control of Boards slow to recognise their important services, is daily shown to be susceptible of improvement. The time for improvement has now arrived, and remains in the hands of the vestrymen of St. George's, from which Board, composed chiefly of enlightened men, we may expect, if not acceptance of the proposition now laid before the members, at least reasons for the refusal, or that some modification of the existing system should be suggested.

It will be seen at once that this is far from being a local question; it is one affecting the public generally. The epidemics which have appeared amongst us from time to time having been proved capable of eradication, and the cause having been made apparent, the prevention is attainable, and, we think, lies now in the hands of the public themselves.

THE PRECIPITATION OF SILVER BY COPPER.*

By ALFRED TRIBE, F.C.S.

WHEN a piece of copper foil is metallically connected into a piece of silver, and placed into an aqueous solution of cupric nitrate (dilute to about 6 per cent) containing air, the oxygen of the latter slowly combines with the copper of the nitrate, forming cuprous oxide, which deposits on the silver in a fine crystalline condition, whilst the nitric element combines with metallic copper, reproducing the nitrate. If the copper have its surface covered with crystalline silver, the decomposition of cupric nitrate by free oxygen is accelerated, so much so that, when this couple is moistened with the salt and exposed to air or oxygen, the tips of the silver crystals become at once coated with cuprous oxide; and when a limited quantity of air is used, nitrogen only remains in the free condition (Gladstone and Tribe, *Proc. Roy. Soc.*, vol. xx., p. 290).

In carrying out the above and other experiments, it was frequently necessary to completely precipitate silver from the nitrate by copper, and it was observed that the metal so obtained, after being washed with water, invariably contained copper, sometimes in considerable quantity. Since the above-mentioned couple is formed the instant silver in solution is brought into contact with copper, the idea suggested itself that the copper found in silver precipitated by that metal might be due to dissolved oxygen in the silver solutions; or to the absorption of that gas, by the liquid, from the air during or subsequent to the precipitation of the metal. The experiments made with the view of ascertaining the correctness of this supposition are tabulated below.

There was employed in each experiment an excess of copper, and in experiments C to I about the same volume of liquid. In A and B, pieces of copper of the same dimensions were placed in open basins and covered to about a quarter of an inch with ordinary silver nitrate, *i.e.*, impregnated with air. In C, D, and E, bottles were filled with ordinary silver solution and stoppered during the precipitation. In F and G, carbonic anhydride was bubbled through the solutions prior to the immersion of the copper plate, and the precipitation conducted as in C, D, and E. In H and I ordinary solutions were employed.

* Read before the British Association, Brighton Meeting, Section B.

Experiment.	Per cent of AgNO ₃ in Solution.	Duration in Hours.	Copper in Precipitated Metal.	Copper per 100 parts of Precipitated Metal.
A.	1.4	24	0.0185	7.45
B.	1.4	48	0.0377	15.23
C.	3.5	24	0.0103	0.32
D.	1.4	24	0.0096	0.77
E.	0.7	24	0.0099	1.61
F.	3.5	24	0.0025	0.08
G.	1.4	24	0.0029	0.23
H.	3.5	1/2	merest trace	—
I.	3.5	1/2	" "	—

It appears, from experiments A, B, and D, that the quantity of copper is increased by exposing the couple covered with a solution of cupric nitrate to the air, and diminished by precipitating in closed vessels. The actual amounts of copper in C, D, and E being nearly the same, indicate that its presence cannot be attributed to oxygen in the copper employed; and, moreover, is a result which would follow were it caused by dissolved oxygen in the silver solutions, since it is probable they each contained about the same quantity of the gas. Experiments F and G show that the effect of saturating the solutions with carbonic anhydride prior to precipitation is to diminish the amount of copper three to four times, which doubtless is due to the partial displacement of oxygen by the more soluble gas. In experiments C to G, there existed a trace of silver in solution after the twenty-four hours. H and I, being of short duration, an excess remained; and it is noticeable that, in every case where the silver was nearly exhausted, copper was found, whereas, where there was an excess in solution, the merest trace only of copper existed in the precipitated metal.

It appears from the foregoing experiments that free oxygen is intimately connected with the presence of copper in silver precipitated by that metal; but, whether copper exists therein as cuprous oxide or as basic nitrate, would depend upon at what stage of the operation the oxygen plays its part. If the two actions, *i.e.*, decomposition of silver nitrate by copper, and cupric nitrate by oxygen, be simultaneous, basic nitrate should be found. If, however, the decomposition of cupric nitrate be not effected until the silver nitrate is so exhausted as to be incapable of action on the produced cuprous oxide, that substance should be found. One experiment made on this point with a weak solution of silver nitrate, seemed to show that basic nitrate of copper did not exist.

INFLUENCE OF CHANGES IN BAROMETRIC PRESSURE ON ANIMAL LIFE.

M. BERT continues, in *Comptes Rendus*, his account of researches on this subject.

Having previously shown that the effects produced on animals by changes in barometric pressure were due almost exclusively to the action of the surrounding oxygen (where the air was not confined), he proceeds to describe some experiments with reference to the effect of diminution of pressure on gases contained in the arterial blood.

His mode of experiment was, briefly, as follows:—The animal (a dog) was put in a sheet-iron chamber having several light ports, and fastened to one of its sides. An artery was uncovered and pinched (so as to interrupt the flow) by pincers which could be manipulated from without the chamber. A tube was introduced into the artery, and it extended to the outside, giving a passage for the blood. The chamber was then carefully closed, and the pressure gradually diminished with the aid of a steam-engine. By an arrangement of tubes and cocks, a current of air chemically pure could be kept up about the animal. The pressure in the apparatus could be reduced to 15 centimetres.

The blood was withdrawn with the aid of a syringe connected with the artery-tube, the pincers having been opened. M. Bert here points out an accident which precautions must be taken to avoid, *viz.*, the passage of air into the animal from without, when the pressure has been reduced to a certain point.

The artery chosen was generally a carotid, sometimes a femoral, and the idea that there is a great difference in the blood of these arteries, as regards richness in oxygen, is considered by M. Bert erroneous.

The gases were extracted from the blood by M. Alvergniat's mercury-pump.

M. Bert gives a table of numbers, showing (in cubic centimetres) the volume of the gases per cent (centimetres) of the blood for various pressures. He makes the following inferences from the numbers obtained:—

(1). When the pressure diminishes, the quantity of gas contained in the blood also diminishes. Hence, when a man rises in a balloon, or climbs a mountain, the quantity of oxygen in his blood, for animating the tissues and compensating expenditure of force, becomes smaller and smaller, and, by and by, insufficient, so that he cannot pass a certain limit without asphyxia. A similar diminution takes place in the carbonic acid, though the consequences of this are not so intelligible. It is at least an erroneous assertion (sometimes made) that the functional sufferings experienced on high mountains are due to intoxication by carbonic acid dissolved in too great proportion in the blood, seeing the proportion of this gas always diminishes with the barometric pressure, whatever the animal's motions.

(2). The diminution in the proportion of oxygen becomes manifest from 20 centimetres' diminution of pressure. And yet these are conditions in which millions of human beings actually live, *e.g.*, on the Mexican plateau of the Anahuac. They are, to use the expression of Dr. Jourdanet, who has studied the physiological effects of such conditions, *anoxymies*; and the objections which have been urged to his ideas regarding them fall away before direct analysis of the gases in the blood.

(3). In most cases, the oxygen diminishes in greater proportion than the carbonic acid. But there were, in this respect, and in respect of absolute diminution, differences in different animals which are not easily explained: differences which doubtless exist in human beings also, and may partly account for the fact that some men can bear with impunity diminutions of pressure under which others become ill and unfit for work. Taking, as an example, a pressure of 36 centimetres, the loss of oxygen was, in four separate cases, 36, 38, 42, and 56 per cent. Carbonic acid presents more irregularities than oxygen.

(4). The chemical combinations of gases in the blood are dissociated very readily, and in a progressive manner, under the influence of diminution of pressure, and it is remarkable that such diminution takes place more readily in the organism than in experiments made *in vitro*.

M. Bert has hitherto treated of gentle and gradual changes of barometric pressure. He next makes a digression to consider the dangerous consequences of sudden changes in the direction of *decompression*. The fact of such danger is well known in the experiences of workmen who work under pressure, such as divers, who, in many cases, have suffered sharp local pains, paraplegia, paralysis, and even death from this cause. M. Bert cites two explanations which have been given of such effects. One is that of M. Rameaux, who considers that the normal gases of the blood, being dissolved in greater quantity in the liquid at high pressure, return to the gaseous state when the pressure is reduced, obstructing the passage in the blood vessels, and causing the same danger as an injection of air into the veins. M. Bouchard takes a different view; he thinks that when the intestinal gases, diminished in volume through pressure, and replaced in part by the blood, which then tends to the abdomen, expand suddenly on decompression, the blood is violently driven through the circulatory system, and the sudden irruption produces

in various organs, especially the nervous centres, apoplexy and congestion.

M. Bert put a healthy cat in a large receiver, the pressure in which was then raised to 8 atmospheres in about half an hour. A large cock was then suddenly opened, and equilibrium ensued in a few minutes. The apparatus was opened, and the animal came out apparently uninjured; but in about ten minutes it was seized with complete paraplegia, along with paralysis of the bladder. The urine contained blood and spermatozooids. Next day, this state continued, and the paralysis made progress. The animal was then killed, and the dorso-lumbar region of the spinal cord was found soft, like cream, without, however, any trace of sanguineous effusion or congestion.

Having in no case met with such a state of the nervous centres as M. Bouchard's hypothesis supposes, M. Bert also found the other hypothesis confirmed by the observation of numerous small bubbles of gas disengaged in the blood on decompression. He analysed this gas, and found it composed of 70 to 90 per cent nitrogen, the rest carbonic acid.

According to the pressure, and the rapidity of decompression, the gas may be suddenly liberated in large quantity, or may only pass to the æriform state by bubbles more or less numerous. In the former case, circulation being arrested, death ensues almost instantaneously, the animal giving some cries and convulsions. The heart and vessels (especially the right side of the heart and the venous system) are then found filled with a kind of froth. The capillaries are injected with gas.

In the latter case, the phenomena vary according to the point at which the gaseous bubbles come to arrest the circulation; sometimes there is only a temporary pain, or failure of locomotion; but very often there was paraplegia, or paralysis, or cerebral disorder, with rolling of the eyes and symptoms of madness. Sometimes even death took place.

In no case in which paralysis had lasted more than an hour was it curable, though the animal sometimes continued to live eight days after. On examination, it was always found that the dorso-lumbar region had been the first attacked, the spinal cord being then softened. The rapidity of this softening, through arrest of circulation, M. Bert considers an important fact for pathological physiology. When the pressure did not exceed 5 atmospheres, decompression might take place in two or three minutes without apparent injury; from 6 atmospheres disorders were caused, and from above 7 atmospheres these always became fatal. When the maximum pressure of the apparatus was produced (10 atmospheres), paralysis and death could not be avoided, unless by extremely gentle decompression. Five minutes per atmosphere was not sufficient to prevent serious injury. Slight and short paralysis was sometimes even caused in a decompression of ten minutes per atmosphere, in descending from 10 atmospheres to the normal pressure.

The foregoing facts, obtained from experiment with dogs, cats, and rabbits, may, to a certain extent, be applied in the hygiene of divers and others working under pressure. Thus, for about 3 atmospheres sudden decompression is not very dangerous, but from 5 atmospheres the danger increases rapidly; and if divers are brought rapidly up from a depth of 70 or 80 metres, the consequences may be fatal.

Returning to the composition of gases in the blood, M. Bert gives the results of experiments in which animals were subjected to pressures above the normal. A dog was fastened in the interior of a metallic chamber, in which the pressure could be raised to 10 atmospheres at a rate of about five minutes per atmosphere. The blood was drawn from the carotid by a method similar to that already described. Such blood was always redder than the blood from the same part at normal pressure; and from about 4 or 5 atmospheres upwards it contained a number of small isolated bubbles.

The gases were afterwards extracted, and a table of numbers is given, from which M. Bert makes the following deductions:—

(1). The richness of the blood in oxygen increases with the pressure; but the increase is very small, and contrasts with the diminution of oxygen where the pressure was diminished. This would seem to indicate that the combination of oxygen with hæmoglobin is at the maximum of saturation, when the pressure is about normal; and for higher pressures, the small additional quantity of oxygen is probably dissolved in the plasma.

(2). The proportion of carbonic acid is not at all affected by increase of pressure; though, as has been seen, it diminishes when the pressure is reduced. M. Bert explains this by the decrease, in percentage proportion, of the carbonic acid in the pulmonary cavities when the pressure is increased, so that its pressure remains the same, and therefore also the quantity of carbonic acid which it maintains in the blood continues the same. In the opposite case (of pressure reduced), the carbonic acid in the lung cavities decreases in pressure, and this is not compensated by increase in percentage proportion.

(3). The proportion of nitrogen increases considerably with the pressure, without exactly following Dalton's law.

PYRO-GILDING AS COMPARED WITH WATER-GILDING.

By J. BAYNES THOMPSON.

THE older method of gilding by means of gold amalgam (called water-gilding) produces excellent results—the colour is beautiful and the coating is lasting; but it has its drawbacks, as most things have—it is a dear method as compared with others, and it is unhealthy for the manipulator on account of the mercury fumes; moreover, it is only applicable to metals that will amalgamate, and therefore is not applicable at all to iron or steel.

When electro-gilding was first discovered, it was thought that this cheap and easy method of gilding would supersede the more expensive and unhealthy method of gilding by means of gold amalgam. This might have been so, and the electro-process did nearly supersede it at first, till it was found out that it was possible to put a mere film on the surface, and that a mere film only was usually put on, though this film could be made to look at first as well as that done by the older process of water-gilding; but there was usually not one-twentieth of the wear in it, not only on account of its thinness, but also on account of its softness. By the old amalgamating process it was not possible to put a film on the surface, for the gold was amalgamated into the surface of the article gilded, and if too small a quantity of the amalgam was applied, then on "burning-out" the mercury, the gold was hidden in the metal of the article gilded, so that there must be a sufficient quantity applied to stand the "burning-out" of the mercury. This is the reason why the under metal does not tarnish through water-gilding as it does through electro-gilding and the older wash-gilding. In fact, electro-gilding has so degenerated, that no better results are expected from it than from the old dipping process, which is simply depositing a film of gold on the article by chemical action through dipping it in a solution of gold that will act chemically on the article. But iron and steel cannot be gilded by dipping, though it be in a solution of gold which will act on the iron or steel, because the gold is thrown down in powder with the salt of iron mixed with it, and will wipe off. Though gold and most other metals can be deposited in a reguline form on iron and steel, as indeed they can on black-lead and other forms of carbon, yet the coatings will not adhere, for the reasons before stated in a description of pyro-plating. Now, if a sufficiently thick coating of gold could be afforded to make an independent sheath to

the article, it would then not come off till ruptured, though it would be still only a loose sheath, and would be a very bungling expedient; moreover, it is out of the question as regards gold and the other precious metals.

With copper this can be afforded; therefore it is resorted to when it is required to gild or silver iron or steel. But such articles are with difficulty polished without raising the coating; and if polishing be successfully accomplished, very shortly the coating blisters up, from the gases generated under it by the action and reaction of the copper, iron, and the salts between them, which always remain less or more according to the cleanness and porosity of the iron.

Thus it is seen that no method of gilding hitherto in use is applicable to steel or iron; but, for all metals that will amalgamate, no process is superior in result to water-gilding when a gilding thickness only is required, but then the cost is great and the process unhealthy. When a thicker coating is required on amalgamating metal, then the electro process or the pyro process may be used. Good results may be obtained by the electro process if carefully and conscientiously done; but by the pyro process good results must be obtained, for the gold is then put on in successive coatings, and each coating is burnt in before the succeeding coating is put on. By this method, there is no danger of the gold peeling after being finished, for if the process is not thoroughly carried out, it will peel in the furnace long before the heat is raised to 500°.

This method recommends itself more especially for gilding or plating with gold on iron and steel, as there is no other that will accomplish that; and it is superior for other metals, in some points, to any other process, to water-gilding in cheapness and healthiness, and to other methods in results.

The mode of operation is similar, in most respects, to pyro-silvering, which was described in this journal some time ago. The only difference is this: the gold is put on in successive coatings, while the silver is all put on at once. Even it is better to put silver on in successive coatings in many cases, and it is sometimes done, but it enhances the price of coating too much to be generally practised with silver; in the case of gilding it is absolutely necessary.

The process is this:—After the article has been thoroughly cleaned, mechanically and chemically, the first coating of gold is put on, which, to all appearance, is a perfect coating; but when it has passed through the furnace, if the article be of steel or iron, the gold has disappeared into the steel, &c., which appears just slightly tinged with yellow. The next coating, after being burnt in, changes from brilliant gold to a much paler tint; but the third coating comes out of the fire as brilliant as it went in, and this is the test that the gilding is complete. For gilding, nothing more is required but a good hard burnishing with a steel burnisher to harden and polish the gold; but if, for any special purpose, a thicker coating is required, as many more coatings are put on as are deemed necessary.

THOUGHTS ON THE CONSTITUTION OF MATTER.

By CHARLES THOMAS KINGZETT.

CHEMISTRY teaches us that there are met with in nature sixty-five kinds of elementary matter; but it does not limit the number to sixty-five, as there may be elements as yet unknown—and there are two properties at least common to all elements, viz., weight and form.

It being one of the objects of chemistry to show the relations existing between different bodies, it was not at all unnatural that Prout should have pointed out what he considered to be *one* of these existing relations, which was "that the numbers which represent the combining proportions of the different elementary bodies are multiples

by whole numbers of the combining proportion of hydrogen;" and the experiments of Dumas seemed to justify, to a certain extent, Prout's idea, although more recently Stas, by a series of most careful experiments, arrived at a different conclusion, viz., that there is no simple relation between the atomic weights. However this may be, one cannot help reflecting on other existing relations between elementary bodies, and thinking with Miller ("Inorganic Chemistry," vol. ii.), "it is not absolutely impossible that the various bodies at present regarded as elementary may, in reality, be compounds of a single primordial substance condensed in different degrees in the various so-called elements." And it is remarkable that this idea, in a modified sense, has existed in the minds of many of the greatest philosophers throughout all ages.

I now propose to state some of the considerations that lead to the conclusion that all matter, simple or compound (so-called), is constituted of one element under different molecular forces. We say that *this* body is different to *that* body because we know the properties of each are distinct or peculiar; but if by some operations a certain substance had its properties changed, the question arises, Should it be still regarded as the original substance?

Now, by the passage of electric sparks through moist air or oxygen, a body is formed which has a peculiar fishy smell, great oxidising power, and various other peculiar characteristics. In short, it is *transformed* into ozone, or the same matter under different molecular forces. And why should we question it as a transformation? for if a force, or forces, can cause the union of two elements, and the compound formed is no likeness of its constituents, why may not a force, or forces, act on *one* matter or element, and the resultant bear no likeness to the original matter?

Again, magnesian borate ($3\text{MgO} \cdot 4\text{B}_2\text{O}_3$), as found in nature, has no developed electric power; but, when it is heated, it is rendered electric. Here, then, a new property is conferred upon it. By some other methods, known or unknown, a second new property might be assigned, and a third, and so on till all its natural properties by which we originally knew it were changed. Should it still be regarded as boracite? I think not.

It is needless to multiply instances, as many parallel and more convincing cases will suggest themselves.

A second consideration, which leads to the conclusion that there is only one primordial substance, is the fact that many simple bodies have properties very much like those of each other. To quote the words of Miller, in regard to the halogens, "it is impossible not to be struck with the close analogy presented by the three elementary bodies, chlorine, bromine, and iodine, both in their uncombined state and in their compounds. The specific gravity, fusing-point, and boiling-point of these elements rise as the atomic weight increases," and "the intensity of their chemical activity decreases as the combining number increases."

See, also, how the metallic bodies fade into the non-metallic bodies, and animal life into vegetable life!

Such and other evidence seem to lead us to consider all the simple known and unknown substances to constitute a series, each member being connected or related to the next by a tie, or ties, and having, as a whole, a gradation of certain properties; each being composed of the same and only elemental matter, but each being differently operated upon by natural molecular forces. So that, on this view of matter, a compound would be formed by a uniting force between two or more such differently operated upon portions of elemental matter.

But then we are conflicted by the question sure to be asked, How do you suppose matter to have been operated upon so as to form different kinds? The answer is found in the fact that the forces which constitute the causes were created at the same time as matter was, for, as Dubois Reymond has said, "separately they do not exist."

"No force without matter: no matter without force," is an axiom; and this brings me to another point, viz., of

the interchangeableness of the forces. Heat can be changed into light, and electricity into heat, &c.; and if force admits of transformation, why should not matter, especially when we consider that matter and force are inseparable? It is pleasing to think that perhaps, after all, the dream of the old alchemist was not so wild as it is thought to be; and still more pleasing is it to think that some day it may possibly be realised.

But to return to the subject, iodine, when united with potassium as potassic iodide, will not form with starch its blue iodide; but, if chlorine-water be added, it is immediately formed. Why is this? Simply because when iodine is used, as in potassic iodide, it is under a peculiar force known as chemical affinity, which masks the property that it possesses when free. And so the original properties of elemental matter are merely hid, or modified by the play of the various forces; literally, therefore, oxygen is not an element solely, but an element *plus* the various forces that bestow upon it those properties which enable us to recognise it as oxygen, and distinct from hydrogen, &c.

The diamond, graphite, and charcoal are constituted of the same matter, though the qualities of each are very different—the difference arising from molecular arrangement, or in other words, from the ultimate particles being differently operated upon.

Finally, let us glance at isomerism in the sphere of organic chemistry. The radical methyl is CH_3 . Ethylic hydride is C_2H_6 . From methyl we can produce its compounds, but we cannot produce them from ethylic hydride; and yet the ultimate composition of the two bodies is the same. Yet we can burn all three forms of carbon into carbonic acid.

Again, propylic alcohol is isomeric with acetone, but yet they are not identical in their properties. So that, if it were asked, Why should some portions of elemental matter be operated upon so differently from others? it might be replied, For the same reason that you cannot get the compounds of methyl from ethylic hydride, and for the same reason that propylic alcohol and acetone are of the same composition and yet so different from the chemists' standpoint.

So that, on the supposition that all forces could be withdrawn, we should have matter reduced to simplicity.

DETERMINATION OF COMBINED CARBON IN STEEL BY THE COLORIMETRIC METHOD.*

By J. BLODGET BRITTON.

In the *Journal of the Franklin Institute* for May, 1870, there is published a description of a colorimeter, together with a modification of the method proposed by Professor Eggertz, for determining combined carbon in iron and steel.

An instrument of the kind there described, but of a little higher range, though in other respects not differing materially from the one originally made and used in the Iron-Master's Laboratory, I now submit to your inspection; and I propose, also, to make some determinations with it for the purpose of showing how quickly they may be made, and enabling you to form some judgment of what reliance can be placed in the results.

Professor Eggertz proposed only a single standard, and the solution to be tested should be diluted to exactly correspond in colour with that of the standard, and the per cent of carbon calculated after carefully noting and making allowance for the measures of water used in diluting.

In practice, difficulty was found in bringing the colour of the normal solution down to the exact shade of the

standard, also other difficulties were met with in conducting the process, causing delay, and interfering with the accuracy of the results.

To materially overcome these, and after numerous attempts, an instrument such as is now before you suggested itself to me; and also I concluded to use a larger quantity of metal than directed by Eggertz, and in addition, to filter the solution from its insoluble matter before making the comparison; and, more recently, to use an acid of just such strength as would completely dissolve the metal without the application of heat. Experimenting with these changes from the original method, I obtained reasonably good results.

The instrument, you will observe, consists of a series of tubes, sixteen in number, two and a half inches long, and about half an inch in diameter, standing upright, and securely fastened in a light, portable walnut-wood frame, but separated one from the other so as to allow just sufficient space between, to place for comparison the tube containing the solution to be tested. The tubes are filled with water and alcohol coloured with roasted coffee, and hermetically sealed. The solutions have been accurately standardised; the one in the tube to the left has its colour to correspond exactly with one produced by 1 grm. of iron containing 0.05 per cent of combined carbon dissolved in 15 c.c. of nitric acid. The solution in the tube next to it has its colour to correspond with one produced by the same quantity of iron dissolved in the same measure of acid, but containing 0.07 per cent of combined carbon; and so with each of the other tubes increasing 0.02 per cent of carbon, coloured in regular succession to the right, the last reaching 0.35 per cent, as indicated by the figures on the upper rail of the instrument.

On the back of the instrument strong pure white paper is tightly stretched for the purpose of screening and diffusing the light, and making the difference in the shades of colour most apparent.

The process of making a determination is exceedingly simple, and may be completed in thirty minutes. 1 grm. of the metal finely divided, is put into a tube of about an inch and a half in diameter, and 8 inches long, with 15 c.c. of chemically pure nitric acid of 1.42 sp. gr., and 2 parts water. The solution is then filtered into a small tube of 4 inches long, and of precisely the same diameter as those in the colorimeter, and as soon as the temperature has become reduced to that of the atmosphere, the tube may be placed in the instrument, the comparison made, and the percentage of carbon at once read off.

While conducting my experiments I found that with three determinations there was usually no perceptible variation, though sometimes there was as much as 0.01 or 0.02 per cent due mainly to some of the metal remaining undissolved. I consider it important, however, that the operator should make his determinations always with a uniform weight of metal and measure of acid, and under like circumstances, and the same as when he made his standards. The acid used should be invariably of the same strength. A very strong acid acts imperfectly on the metal; one not quite so strong acts too violently, and causes too much loss of colour; while, on the other hand, a very dilute acid leaves much of the metal undissolved. I have obtained good results from one of the strength already indicated. From twenty to twenty-five minutes is usually sufficient time to dissolve the metal, and from three to five minutes more to filter. The metal should be in moderately fine division, and passed through a sieve of about 20 spaces to the inch, to insure a pretty uniform size of particles, and about the best suited for being acted on by the acid. The solution, which always becomes quite warm from the action of the acid on the metal, should be allowed to cool to the temperature of the atmosphere, and the colour to become fixed before the comparison is made; the cooling may be hastened by immersing the lower end of the tube in cold water; but a considerable time should not be lost, for after some hours,

* Explained and conducted before the American Institute of Mining Engineers, at the New York Meeting, May 22, 1872.

and sometimes less, a change occurs, and a gradual loss of colour becomes apparent, and for this reason a nitric acid solution of metal cannot be used for a standard.

I think that by observing these precautions, the operator can, after a little experience, obtain results by the method described, and with the so-called mild steels, sufficiently accurate for all ordinary metallurgical purposes, and, by using a number of tubes at the time, make more than a dozen determinations in an hour.

The speaker then proceeded, in the presence of the members, to make three determinations according to the method he described. When the solutions were filtered and ready for comparison, Professors T. Sterry Hunt and G. W. Maynard were asked to make the comparisons, and declare the results. The solutions were found to be alike in colour, and to be between 15 and 17 of the instrument. The amount of carbon in the metal had previously been accurately determined by another method, and found to contain a little over 16 per cent.

The speaker concluded his remarks by stating that he had carefully tried several of the combustion methods, but had found the one known as Ullgren's, with some modifications, to afford the most constant and reliable results, and he preferred it, in his own practice, when a high degree of accuracy was necessary.

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.*

By Dr. F. CRACE CALVERT, F.R.S.

(Continued from p. 117).

Quercitron, Fustic, Persian Berries, Weld, Aloes, Turmeric, Annatto, Ilixanthine, Lo-kao, Tannin Matters—Gall Nuts, Sumach, Divi-Divi, Myrobalans, Catechu.

I SHALL have the pleasure of devoting the first part of this lecture to some of the most useful and important yellow substances used by dyers and calico-printers, and to one or two other colouring matters which, although scarcely commercially important, are interesting from a scientific point of view.

Among the most valuable of these bodies is *quercitron*, the bark (from which the epidermis has been removed) of a particular species of oak, called the *Quercus nigra* or *Quercus tinctoria*. This tree is indigenous to the United States of America, and is especially found in the forests of Pennsylvania, Georgia, and in North and South Carolina. A chemist, of the name of Bancroft, first introduced it to the English dyers in the year 1775. The most esteemed qualities are those imported from Philadelphia, New York, and Baltimore. The bark, after being removed from the tree, is dried, and ground between mill-stones. The value of a sample bears a direct ratio to the fineness of the powder, for the woody fibre of the bark, which contains only a small quantity of colouring principle, is not easily reduced to a fine powder.

M. Chevreul was the first chemist who examined this dye, and he found it to contain a peculiar tannin, which has since received the name of *quercitannic acid*, and a yellow colouring principle, to which he gave the name of *quercitrin*, but which has since received the name of *quercitrinic acid* from M. Bolley.

M. Chevreul, by boiling quercitron bark in water, and allowing the aqueous solution to stand, obtained fine, laminated crystals, which were gradually deposited, and to which he gave the name of quercitrin.

M. Bolley followed a better process. He treated the bark by alcohol, precipitated the tannin from the alcoholic solution by gelatine, evaporated the alcohol, and obtained the quercitron under the form of colourless crystals. These, under the influence of air or oxidising

agents, assume a bright yellow colour. The alkalis give quercitron a brownish tint, but its most characteristic property is to give a greenish-yellow precipitate with chloride of iron, and a beautiful bright yellow precipitate with protochloride and oxymuriate of tin.

M. Rigaud discovered, a few years since, by boiling quercitron with water containing 10 per cent of sulphuric acid, that it is a glucoside, which decomposes under the influence of the acid into glucose and quercitrin according to the following formulæ:—

Quercitrin is a crystalline powder, of a bright lemon colour, and of a much richer hue than quercitron. It has no taste, is insoluble in cold water, and only slightly soluble in hot, but is freely soluble in alcohol. It is soluble in alkalis, to which it communicates an orange-yellow hue. Its alcoholic solution gives orange precipitates with the salts of lime, baryta, and lead. It assumes an orange colour with perchloride of iron.

Although quercitron bark gives a fine yellow colour on woollen goods, when mordanted with salts of tin, to which has been added alum or cream of tartar, still its employment has greatly decreased of late years, owing to its colour assuming a reddish hue when exposed to the atmosphere.

Within the last twenty years, a preparation from it has been imported into this country from America, under the name of *flavine*, which in reality may be considered as commercial quercitrine. It is now manufactured in England by two different processes. The first consists in boiling half a ton of quercitron bark with 63 lbs. of soda crystals, in about 2000 gallons of water; after boiling for about a quarter of an hour, 250 lbs. of concentrated oil of vitriol are added. The whole is then maintained at the boil for two hours, when it is run off on to woollen filters, washed until free from acid, pressed, and dried, and is ready for market. The second process, which I consider the better one, consists in boiling for two hours 100 parts of quercitron bark with 300 of water and 15 of oil of vitriol, and then washing, pressing, and drying, as in the first process. 100 parts of quercitron bark give 85 of flavine, which have a dyeing power equal to 250 parts of quercitron.

Flavine is not much employed in calico printing as a yellow dye, its principal use being to communicate a brown and orange hue to madder reds.

The best mode of estimating the value of a sample of quercitron bark or flavine, is to dye some mordanted cloth in the same way as in testing the value of a madder or garancine.

We shall now pass to the study of another colouring matter, called *old fustic*. The tree which supplies it is called *Morus tinctoria*, and grows in Madeira, Mexico, Jamaica, Cuba, and other islands of the West Indies. It arrives in this country in logs of various sizes. Dyers prefer those which are dense, are not worm-eaten, and which are of a fine orange-yellow tint in the inside.

In this case, again, my master, M. Chevreul, was the first to isolate the two colouring matters which the wood contained. To the first of these Wagner gave the name of *morintannic acid*, and to the second that of *morinic acid*. To extract these, rasped fustic is boiled twice with water and the solution concentrated to the state of a syrup, when after a few days a crystalline deposit takes place, which is separated, washed rapidly with cold water, and pressed. To separate the two colour-giving principles, the pressed mass is treated with boiling water, which leaves the morinic acid as an insoluble mass, while the morintannic acid is dissolved. The morinic acid is treated with weak hydrochloric acid, to remove some lime salts; it is then dissolved in alcohol, from which it crystallises in the form of yellow needles. To obtain the morintannic acid which was dissolved, the solution is concentrated, when the colouring matter crystallises

* The Cantor Lectures, delivered before the Society of Arts. Revised and communicated by the Author.

out, and only requires re-crystallising once or twice from acidulated water to give it almost pure. It forms yellow crystals soluble in alcohol, which have the formula $C_{13}H_{10}O_6$. It gives a greenish black precipitate, with sulphate of protoxide of iron, and, with salts of lead, a yellow precipitate, soluble in acetic acid. It is decomposed by concentrated alkalis, and when boiled with zinc and sulphuric acid, the solution assumes a very bright red colour, due to the transformation of morintannic acid into two most interesting substances, *phloroglucine* and *machromine*.

Moric acid, though insoluble in water, is freely soluble in alcohol and ether, but is insoluble in bisulphuret of carbon. It is soluble in alkalis, to which it gives a yellow colour, and from this solution it is re-precipitated by the addition of an acid. Perchloride of iron communicates to its alcoholic solution an olive-green shade. It gives yellow precipitates with salts of zinc, tin, lead, and alumina, and a dark green precipitate with copper. It has the formula $C_{12}H_8O_5$.

Old *fustic* is especially employed for dyeing wools in yellow or olive-green shades. They are mordanted with a salt of alumina for yellow, or with a salt of iron for green. By the employment of salts of copper and other mordants a variety of shades can be obtained. It is much used by dyers, but only to a limited extent by calico printers.

Young *fustic* belongs to the same genus as sumach, of which I shall speak further on, and its botanical name is *Rhus cotinus*. It grows in the West Indies, and in France and the southern parts of Europe. It is found in commerce in the form of small logs and crooked branches. Young *fustic* contains a tannin matter and three colour-giving principles, a red, a brown, and a yellow. The yellow colouring matter, when isolated and crystallised, bears the name of *fustine*. It is soluble in water, alcohol, and ether. Alkalis communicate to it a fine orange hue. It rapidly oxidises when exposed to the atmosphere, assuming an orange colour. A decoction of the wood is affected by the alkalis and air in the same manner as *fustine*. It gives a bright orange precipitate with lime and baryta waters, and a similar coloured precipitate with chloride of tin. Persulphate of iron yields with it an olive-green precipitate. Young *fustic* dyes wool mordanted with salts of alumina a fine orange colour, but it is easily affected by light; its chief employment is in conjunction with cochineal, to the red colour of which it imparts a brilliant orange hue. It is much used in Turkey and the Tyrol by tanners to impart to their leather an orange-yellow colour.

Persian berries, which are extensively employed by woollen and mixed fabric dyers, calico printers, paper stainers, and leather dressers, are the berries or fruit of a genus of plants called *Nerprun*, which grows freely in France, Spain, Turkey, Persia, &c. Generally speaking, the berries are gathered before they are quite ripe, which is the reason why the berries, which are the size of a small pea, have a yellowish green shrivelled appearance. The berries only give good results when recently gathered; after one or two years they lose a great deal of their value, not yielding to the dyer such brilliant hues. The yellower they are, the less price they command in the market. They bear among the dealers the names of the countries from which they are imported; thus there are Avignon berries, Spanish berries, Turkish berries, and Persian berries. The latter are the best, and are obtained from the *Rhamnus amygdalinus*. Among dyers and calico printers all the varieties are called Persian berries.

The yellow decoction of the berries assumes an orange-yellow tint with alkalis, which is not changed on the addition of an acid. Lime-water gives it a greenish hue, persulphate of iron a greenish yellow. Chloride of tin gives a greenish yellow colouration, and a slight precipitate.

Sir Robert Kane succeeded, some years ago, by treating the berries with ether, in extracting a substance, crystallising in fine golden yellow crystals, to which he gave the name *Chrysorhamnine*, and assigned to it the formula $C_{23}H_{11}O_{11}$. He found that, when a solution of this compound was boiled in the air or in presence of an oxidising agent, it became converted into a substance which he named *xanthorhamnine*, to which he gave the formula $C_{23}H_{12}O_{14}$.

Since then, several eminent chemists have examined into the nature of these colouring matters, among whom may be mentioned Gellatly, Bolley, and especially Lefort and Schützenberger.

From their researches the following facts may be gathered. Lefort, in 1866, succeeded in isolating two colouring matters from the berries, which he named *rhamnagine* and *rhamnine*. *Rhamnagine* is soluble in water, and may be obtained under the form of crystals, while *rhamnine* is an insoluble yellow amorphous powder. In researches, published in 1869, he found that *rhamnagine* was identical in composition with *rhamnine*, and that only a molecular change took place in the transformation of *rhamnagine* into *rhamnine*, such as we are all aware starch undergoes on conversion into dextrine. He supported this view by analyses, showing that both these substances had the same formula, namely, $C_{24}H_{32}O_{14}$. The researches of Schützenberger further proved that, under the influence of weak sulphuric acid, *rhamnagine* is decomposed into a peculiar sugar, and a substance to which he gave the name *rhamnatine*, thus showing that *rhamnagine* is a glucoside. The following formulæ show the decomposition which takes place:—

From these results it would appear that the real colour-giving principle is *rhamnagine*, and that *rhamnine* and *rhamnatine*, which are insoluble in water, are only products of decomposition.

Decoction of Persian berries is principally used in print works for producing bright yellows and greens, on prepared tin cloth, in steam styles. To obtain yellows, the extract is mixed either with a little red mordant (sulphoacetate of alumina), or with a little muriate of tin. The mixture is thickened, printed on, and the fabric is steamed. To produce greens, the decoction of berries is mixed with prussiate of tin, the mixture is thickened and printed on the fabric, which is then steamed, when the yellow of the berries and the Prussian blue which is formed, unite to produce green on the fabric. The decoction of berries is very apt to enter into fermentative decomposition, and thereby become ropy; this may be prevented by the addition of a little carbolic acid.

A very fine brilliant yellow lake is produced from a decoction of Persian berries, the manufacture of which was kept secret for a long period by the Dutch. It consists in adding pure carbonate of lime to the decoction, when the lime salt falls, carrying with it the colouring matter of the decoction. The yellow lake thus produced is moulded into small lumps, which are dried in the shade.

There is a variety of mignonette which used to be cultivated in England and France, called weld, its botanical name being *Reseda luteola*. This plant yields a most valuable yellow dye when fixed on wool by means of alum, not only because the colour is exceedingly brilliant, but because it is very solid, resisting light, heat, and acids. Alkalis only communicate to it a slight orange tint. Its colouring matter was extracted by M. Chevreul many years ago, and he gave it the name of *luteoline*. He obtained it in yellow transparent crystals. By the action of oxidising agents, such as bichromate of potash, it assumes a magnificent yellow tint, identical to that produced with it in cotton fabrics.

M. Moldenhauer has since studied luteoline, to which he assigned the formula $C_{20}H_{14}O_8$. It is slightly soluble in water, but very soluble in alcohol. It dissolves without decomposition in strong sulphuric acid, and yields, even when greatly diluted with water, a fine green colour with perchloride of iron. Schützenberger, who has lately studied this body, states that when mixed with water and heated to a temperature of $480^{\circ}F$. in sealed glass tubes, it decomposes into what he considers pure luteoline and resin. The luteoline is found in crystals adhering to the sides of the tube, while the resin collects at the bottom. He states, also, that if a decoction of the berries is boiled with weak sulphuric acid, a new yellow colouring matter is produced, which possesses a high dyeing power as well as a pure yellow hue.

The introduction of quercitron and flavine is the principal reason why weld has nearly disappeared from the market.

Aloes is imported into Europe from Bombay, Barbadoes, Jamaica, and the Cape of Good Hope, in the form of resinous masses, varying considerably in size. It is the dried sap or juice of several varieties of aloes, of the family of *Asphodels*.

Dr. Stenhouse, who has examined this substance, has succeeded in isolating two compounds; one, which crystallises in yellow prismatic needles, is soluble in cold water and alkalies, the solution having an orange tint. It has an intensely bitter taste. He has given it the name *albine* and assigns to it the formula $C_{17}H_{18}O_7$.

The second compound, which may be considered as the resin of aloes, has received the name of *aloetine*. Dr. Schunck has produced from aloes a yellow dye, called *chrysammic acid*, which will probably be yet extensively used. It is prepared by heating in a water-bath 8 parts of nitric acid with 1 of aloes; when the violence of the action has ceased, a second part of aloes is added. The application of heat is continued until hyponitric fumes cease to be given off. The mass is then poured slowly into a large bulk of water. The *chrysammic acid* falls in flakes to the bottom of the vessel. These are washed with water, until it assumes a fine purple colour. The formula of this acid is $C_7H_2(NO_2)_2O_2$. It forms small golden-yellow scales, soluble in alcohol and ether. Although but sparingly soluble in water, it communicates to it a magnificent purple tint, and its dyeing power is considerable. Mr. Saac has made a great number of dyeing experiments with *chrysammic acid*, and has produced with it a variety of shades. He believes that one day they will become commercial.

Turmeric is the tube or underground stem of the *Curcuma longa*, a plant which grows abundantly in the East Indies. It is imported principally from Bombay, Java, Batavia, and Barbadoes. That from Bombay is the most valuable. It is ground and sold to the dyers in the state of a fine powder of a remarkably brilliant orange hue, and of a strong odour. Vogel and Pelletier succeeded in extracting from it a colouring matter, to which they gave the name of *curcumine*. M. Lepage has, however, given the best process for its extraction. The ground roots are treated with bisulphuret of carbon, which dissolves a volatile oil and resinous matters. The root is then dried and acted on by a weak alkaline solution, which dissolves the *curcumine*. To liberate it, the alkaline solution is neutralised with an acid, when the *curcumine* falls as a precipitate. This is collected, dried, and dissolved in ether, from which it separates under the form of small brown scales, which yield on trituration a brilliant yellow powder.

Turmeric is seldom used as a dye, owing to its colour being so easily affected by alkalies, a fact well known to chemists, as they often employ it to ascertain the presence of a trace of free alkali or boracic acid in solutions. It is used in India to flavour rice, and by the natives to colour their skin red.

(To be continued).

OBITUARY.

JOHN CARGILL BROUGH.

It is with no formal expressions of regret that we announce the death of Mr. Brough. That he was a man of great refinement and intellectual culture was evinced by the ability he displayed as Editor of the *Chemist and Druggist*, the *Ironmonger*, the *Year-Book of Pharmacy*, and sub-editor of *Nature*; but failing health rendered it necessary for him to relinquish positions he had filled with so much credit. The promoters of the *Laboratory* could hardly have found a more energetic Editor than Mr. Brough, and in his hands that journal bid fair to become a formidable rival of the *CHEMICAL NEWS*; in spite, however, of his untiring zeal the *Laboratory* was not successful; but Mr. Brough was ever the most courteous of opponents. Some time before his death he became principal Librarian of the London Institution, and broken in health as he was, he did much to increase its usefulness, and won the esteem of all with whom he came in contact.

NOTICES OF BOOKS.

On Food. By H. LETHEBY, M.B., M.A., Ph.D., &c., Professor of Chemistry in the College of the London Hospital, and Medical Officer of Health, and Food Analyst for the City of London. Second edition, enlarged and improved. London: Bailliere, Tindall, and Cox. 1872.

THE Cantor Lectures delivered in January and February, 1868, by Dr. Letheby, on food, its varieties, chemical composition, nutritive value, comparative digestibility, physiological functions and uses, preparation, culinary treatment, adulteration, &c., were deservedly popular; and we are glad to see that a second edition has been published, now that the work has for some time been out of print. This second edition contains several important amendments, and if possible is even more valuable than the former.

CORRESPONDENCE.

ASSAY OF PYRITES FOR GOLD.

To the Editor of the *Chemical News*.

SIR,—As you have done me the honour to print in your Journal for August 9, 1872, my article on the "Assay of Pyrites for Gold," I beg leave to say that I hope the method I have there described will be examined by all chemists interested in this kind of work, and that it will be criticised as sharply as it deserves.

On what its value depends I am unable to say. I have sometimes thought that the interior of the crucible being filled all the time with an atmosphere of CO_2 , it may be that the sulphur is volatilised in a stream of gas in which it cannot take fire, and that in consequence the gold is not dissipated. Be this as it may, I am sure that this method in skilful hands will show amounts of gold in many iron pyrites, far beyond the belief of most of the assayers who have examined them in the ordinary way.—I am, &c.,

J. M. MERRICK.

Laboratory, 39, Broad Street, Boston, U.S.A.,
August 24, 1872.

MISCELLANEOUS.

Spontaneous Generation of Doctors.—The following letter appears in the *Lancet* for August 17:—

"SPONTANEOUS GENERATION OF DOCTORS.

"To the Editor of the *Lancet*."

"SIR,—Your able remarks on foreign degrees induce me to request of you a small space to notice the remarkable creation of doctors that has been going on for some time past in the columns of your weekly contemporary, the *CHEMICAL NEWS*. Almost every foreign name in that journal for the last year or two has the prefix of 'Dr.,' and as many of these German and French gentlemen are personally known to me, I can assure you they would be more surprised than pleased if they saw themselves thus decorated by an unknown hand. British subjects, for palpable reasons, are not so honoured. It is clear that the editor is jealous of doctors generally; and in thus creating an abundant and fictitious flock of foreign doctors, he intends, no doubt, to throw a slur upon the titles obtained at foreign Universities by many of your most distinguished professors, and more especially your distinguished chemists. Pray allow me to expose this practice in the columns of your widely-read journal, and believe me, Sir,

"Your constant reader and obedient servant,

"L. STEIN, M.D.,

"Demonstrator of Anatomy in the University of Copenhagen.

"Brighton, Aug. 14, 1872."

It is amusing to find that while L. Stein, M.D., sends this letter to the medical papers, a Th. Kindt, Ph.D., has been sending the same letter to scientific journals (both emanating from Brighton). One gentleman, after reading the letter, took the precaution to look through twenty-six numbers of the *CHEMICAL NEWS*, and out of 883 names of foreign authors he found only 178 having the prefix of "Dr." We would suggest that the Editor of the *Lancet* should have taken some such precaution, and thus have avoided the publication of untruths. In all cases in which we have given the author of a printed paper the title of "Dr.," the title has been copied from the foreign periodical containing the original article. As, however, the *Lancet* is the only journal which has thought fit to pay attention to the dishonourable insinuations levelled against the Editor of the *CHEMICAL NEWS*, and as Mr. Stein is evidently anxious that his remarks should be read by the greatest possible number of scientific men, we have had much pleasure in gratifying him by reprinting his letter with its very sensational heading.

The Royal Polytechnic.—An interesting Lecture on "Coal and How to Save it" is now being delivered at this Institution, by Professor E. V. Gardner. In the course of the Lecture mention is made of Stone's Patent for coating steam boilers. This coating is said to effect an economy of one-third in the employment of coal for driving machinery. The Laboratory of the Chemical Department has been reorganised and newly fitted, and is now opened under the direction of Professor Gardner.

Refractory Clays.—Bischof finds that the analysis of a clay gives a distinct indication as to its power of resisting extreme heats. The temperatures were measured by keeping the clay at a white heat till wires of iron or platinum were fused. The value of a refractory clay is found by the proportion of the alumina to the fusible matter, and again by that of the alumina to the silica. The more alumina a clay contains in proportion to the fusible matter (iron, alkalis, &c.), the more refractory is it. Silica, on the contrary, augments its fusibility. Of two

clays containing alumina and fusible matter in the same proportions, that which contains least silica is most refractory. Save in certain determinate cases, the clays containing alumina, silica, and fusible matter in equal proportions have an equal power of resisting fire. If we give to clays the general formula, $mAl_2O_3 + nSiO_2 + RO$, the degree of resistance to fire is measured by $\frac{m}{n}$. The higher the value of this fraction, the more refractory the clay.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Seances de l'Academie des Sciences, September 2, 1872.

This number opens with excellent speeches from the President, Dr. Faye, and one of the Perpetual Secretaries, Dr. J. Dumas, on the occasion of the presentation of a medal to Professor Chevreul (born August 31, 1786) in consideration of his eminent services to science, industry, arts, and the Academy, during a period of more than sixty years. The eminent speakers give a vivid account of the long and laborious career of the illustrious *savant*, the *doyen* of the Chemical Section of the Academy.

This number contains the following original papers and memoirs relating to chemistry:—

New Method of Extracting the Precious Metals from Copper-Containing Pyrites.—F. Claudet.—The spent or burnt pyrites (Spanish and Portuguese) contains, according to the author, from 0.0020 to 0.0028 per cent of silver (equal to from 20 to 28 grms. to the ton), and, in addition, a small quantity of gold; the extraction of these small quantities might at first sight appear futile, but, as the quantity of pyrites burnt in the United Kingdom alone amounts annually to between 400,000 and 500,000 tons, the extraction of the precious metals therefrom is of importance. The author describes at length a method of operation which is now successfully used in a factory established by him and Mr. J. Phillips at Widnes, near Liverpool; the process is based upon the insolubility of iodide of silver in a solution of chloride of sodium at the ordinary temperature. The burnt pyrites is first ground to powder, sifted, and next gently ignited with some common salt: the ignited mass is, after cooling, treated with dilute hydrochloric acid, and a sufficient quantity of iodide of potassium is added to the clear liquor. In the dry state, the precipitate formed consists, in 100 parts, of—Silver, 5.95; gold, 0.06; lead, 62.28; copper, 0.60; oxide of zinc, 15.46; oxide of iron, 1.50; lime, 1.10; insoluble residue, 1.75; loss and oxygen, 3.62. In the year 1871, at the works above mentioned, 16,300 tons of spent pyrites were operated upon, yielding 333.245 kilos. of silver and 3.172 kilos. of gold, the net value of which, after deducting expense of refining and the loss of 137 kilos. of iodine, was £3230.

Division of One Base between Several Acids when in Solution; Bibasic Acids.—Dr. Berthelot.—The continuation and end of this lengthy essay.

Spontaneous Combustion of a Wooden Beam by the Sole Action of the Solar Rays.—M. Collet.—This short paper contains the account of the spontaneous combustion of a wooden beam in a building at Ribemont (Aisne). The oak beam was found to be on fire during one of the hot days in the summer; it was directly exposed in an open yard to the concentrated heat of the sun's rays; the combustion, although proceeding slowly, was quite distinct; but was not attended with flame; the smoke, however, had a peculiar appearance, and on blowing the wood it burst into flame. The author asserts that the fire was entirely due to the heat of the sun.

September 9, 1872.

This number contains, in addition to several original papers and memoirs relating to botany, meteorology, astronomy, natural philosophy, mathematics, and mechanics, the following original papers bearing upon chemistry:—

Result of the Action of the Sun's Rays upon Various Kinds of Glass.—T. Gaffield.—This paper, to which is added a lengthy appendix by Chevreul, records the results of a series of experiments, continued for several years, on the effect of the sun's rays, and the molecular alterations produced in various kinds of glass by being exposed to these rays for a considerable length of time and under different conditions.

Induction Currents Developed in Gramme's Electric Machine.—J. M. Gauguier.

New Kind of Urinary Concretion Found in Horned Cattle.—G. Roster.—This paper treats on a peculiar urinary deposit first observed by an Italian veterinary surgeon at Pietra-Santa. The crystalline matter is insoluble in alcohol and ether, and yields ammonia when ignited with soda-lime. It smoulders away without flame when heated upon platinum foil over a spirit-lamp flame, leaving a white, porous, very light ash, soluble in water, but not rendering it alkaline, and found to be magnesia; the composition of this material was ascertained to be $C_{10}H_{22}N_2MgO_{14}$, that is, lithurate of magnesia. The free lithuric acid is a solid crystalline body, fusing at 205° , soluble in boiling-hot water and boiling alcohol, but insoluble in ether.

Annalen der Physik und Chemie, von Dr. J. C. Poggendorff, No. 8, 1872.

This number contains the following original papers and memoirs more particularly relating to chemistry:—

Method of Measurement of the Velocity of Rotating Mechanisms.—A. Schuller.

Researches on Fluorescens.—E. Hagenbach.—The continuation and conclusion of this monograph.

Glacial Formation of the Fjords and Alpine Ice Seas of Norway.—A. Helland.

Remarkable Block of Lava Hurlled Upwards by the Late Eruption of Vesuvius.—G. vom Rath.—This memoir treats on the mode of formation and mineralogical characters of a solid piece of lava lately thrown up by the eruption of the volcano.

Researches on the Spectrum of the Aurora Borealis.—H. C. Vogel.

Relation Existing between the Second Axioma of the Mechanical Theory of Heat and the Hamilton Principle.—R. Clausius.

Contribution to our Knowledge on the Thallium Compounds.—C. Rammelsberg.—This exhaustive monograph treats at length on the following compounds:—Hypo-sulphate of thallium, $Tl_2S_2O_8$; equiv. = 568; per cental composition— Tl , 71.83; S , 11.27; O , 16.90. Iodate, $TlIO_3$; equiv. = 379; in 100 parts— Tl , 53.82; I , 33.51; O , 12.67. Di-iodate of thallium (iodate of sesquioxide)— $Tl_2O_3 + 2aq = (TlO_3 + 3I_2O_5) + 3aq$.

Thallium periodate does not exist; with periodic acid, thallium behaves like iron, manganese, and cobalt, all of which become oxidised to a higher degree, while iodic acid is simultaneously formed. Dithallium periodate. Thallium sesquichloride, Tl_2Cl_3 ; equiv. = 514.5; in 100 parts— Tl , 79.3; Cl , 20.7. Dithallium-potassium chloride. Ammonium-dithallium chloride. Potassium-dithallium bromide. Potassium-dithallium iodide. Isomorphism of the thallium salts with that of the salts of monoatomic metals. Perchlorates. Phosphates. Sulphates, seleniates, and chromates. Double sulphates of

the magnesian group. Thallium alum, $Tl_2RS_2O_8 + 24aq$. Carbonate, Tl_2CO_3 . Oxalates. Tartrates. Paratartrates. Picrates. Cyanides.

Description of an Instrument Contrived for the Purpose of Measuring the Thickness of any Substance.—P. Schönmann.—Illustrated by engravings.

New Shape of the Noë Thermo-Electric Element.—Dr. A. von Waltenhofen.

Pressure and Elastic Shock (Elastischer Stoss).—G. Hansemann.

Annales de Chimie et de Physique, September, 1872.

This number contains the following original papers and memoirs:—**Atmospheric Ozone.**—A. Houzeau.—This monograph, elucidated by a large number of tabulated forms, is divided into the following sections:—Historical notices; oxidising power of normal air; smell of normal air; decolourising and disinfectant properties of normal air; meteorological portion; mode of application of semi-iodurated paper; proportion of ozone contained in air; observations made at Ecorchebœuf in 1863; manifestation of ozone according to the seasons; influence of storms and hurricanes upon the manifestation of ozone; origin of atmospheric ozone.

Researches on Dulcete and on Sugars in General.—Dr. G. Bouchardat.—This memoir, the first instalment of an exhaustive essay on this subject, has been already alluded to from the abstracts published by the author in other periodicals; the full account of every experiment and method of research is here published.

New Process for the Volumetrical Estimation of Copper and of Sugar.—F. Weil.—Reserved for translation.

Synthesis of Orcin, and on some of the Sulphuretted Derivatives of Toluene.—G. Vogt and A. Henninger.—Notwithstanding the high scientific value of this essay, its contents are not well suited for any useful abstraction.

Polytechnisches Journal von Dr. E. M. Dingler, first number for August, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Newly-Contrived Water Air-Pump.—C. Christiansen.—The description, illustrated by a woodcut, of a readily-constructed piece of apparatus for use instead of the Bunsen air-pump.

Bunsen Dip (Tauch) Battery.—J. Müller.—This essay is illustrated by a series of engravings.

Validity of the Patent of the Hoffmann Ring Furnace Viewed According to Facts.—Dr. H. Seger.—This memoir, illustrated by several engravings, treats on the legal validity of a German patent. It appears that the invention is an immense improvement in the mode of constructing brick-, lime-, and other kilns.

Composition of the Lyes Obtained by Lixivation and Oxidation of the Soda Waste for the Purpose of Obtaining Sulphur therefrom.—C. Stahlschmidt.—This exhaustive essay is divided into the following sections:—Introduction; this treats, in the first place, on the process of recovering sulphur from soda waste; it also contains a concise review of the different modes of operation proposed and carried out, and a discussion on the nature and composition of soda waste. Estimation of sulphurous, hyposulphurous, and sulphuric acids. Behaviour of the sulphur lye with sulphuric acid. The author observes that he is not enabled to give precise directions for practical use, in consequence of the variation in the composition of the lyes.

Studies for Establishing a Scientifically-Arranged Tanning Method.—A. Reimer.—The continuation of this monograph; this part of the author's memoir contains the following sections:—Skin (corium) and water; skin and lime and other alkaline matter; skin and acids; skin and tannic acid; skin and chloride of sodium.

Boric Acid as a Preservative for Milk and Beer.—A. Hirschberg.—It appears that there has been for some time in Sweden, under the name of aseptic, a mixture consisting of equal parts of boric acid and alum, this mixture being applied for the preservation of meat, and also for protecting it from the injurious action of the oak-wood of the casks in which it is kept. The author states that he found that, by adding 1 grm. of boric acid to a pounds of milk, it remained sweet and fresh in hot summer weather for 120 hours, while milk not so treated became sour and quite useless in 36 hours; the addition of boric acid to milk does not interfere with its use, but the cream is separated far more slowly. Experiments have shown that beer is improved by the addition of boric acid, even if it is kept at a comparatively high temperature.

Protection of Wood from Fire.—F. Sieburger.—After first referring to the inconveniences of the application of chloride of zinc and so-called water-glass solution, the author says that it is preferable to first coat or wash the wood twice with a hot and saturated solution of 3 parts of alum and 1 part of sulphate of iron, and next with a more dilute solution of sulphate of iron, to which sufficient pipe-clay has been added to render it as thick as ordinary oil paint. Another method is the following:—The wood is repeatedly painted over with a hot solution of glue, until a very thin coat of glue remains on the surface; then the wood is painted over with a thicker solution of glue, and a mixture of 1 part of sulphur, 1 part of ochre or pipe-clay, and 6 parts of sulphate of iron, is applied to the wood with a dregder, the ingredients having been first separately pulverised and thoroughly mixed.

Le Moniteur Scientifique Quesneville, No. 369, September, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Revue des Inventions Nouvelles.—A. Jougllet.—This memoir contains the concise description of a series of some thirty new inventions relating to various branches of industry; those of the inventions which relate to chemical science have been already described in our pages. The author, while briefly alluding to Hemptinne's process for concentrating sulphuric acid in vacuum pans, promises to publish shortly a full account of this invention with its latest improvements.

Manufacture of Ultramarine by One Single Calcination.—M. Fürstenau.—This process is based upon the fact that, when an aluminous white ultramarine is first moistened with a solution of resin in sulphide of carbon, and then ignited over a spirit-lamp in a porcelain crucible, blue ultramarine of great beauty is formed. The mixture to be calcined should contain the elements of penta-sulphide of carbon, while the temperature of ignition should be as low as possible. The composition of the mixture to be used on the large scale (woodcuts exhibit the arrangement of the furnace and crucibles) varies somewhat, but the following will, however, give an idea of the composition of the mixture:—Kaolin, previously lightly ignited, and free from undecomposed felspar, 100; soda, 90; sulphur, 120; resin, 10; finely-divided charcoal, 10. The mode of manipulation is described at length, but it appears that the process is attended with technical difficulties, and requires careful workmen to execute it satisfactorily.

Coralline and its Use in Dyeing and Printing.—Dr. Quesneville.—This paper contains an account of the history of invention, present method of preparation, and method of application to cotton and silk fabrics.

Coralline Printing on Woollen Fabrics.—Dr. Kiemeyer.—The detailed description, with receipts for the practical application of printing with coralline on flannels and similar woollen fabrics; the process described is also applicable, with a slight modification of ingredients, for printing coralline on cotton fabrics.

Preservation of Timber.—R. H. Buell, C.E.—This memoir, too lengthy for any useful abstraction, contains an excellent review of all that is known concerning the decay of timber and the causes thereof, as well as a full account of the various processes proposed and tried for its preservation.

New Process of Brewing Beer.—A. Jougllet.—The author describes at length, and illustrates with woodcuts, Pasteur's brew for improvements in brewing, which will undoubtedly tend to make that

process more simple, easier to control, and produce a better yield of beer, both as regards quality and quantity.

Researches on the Part which Sulphurous Acid Plays when Employed to Produce the Saccharification and Alcoholisation (Alcoholisation) of Grain, According to a New Method.—V. Hemilian and N. Melnikoff.—Reserved for full translation.

Researches on Chondrine.—Dr. J. Moleschott and A. Rubini.—After referring to the tests given by the late Berzelius and by Dr. G. J. Mulder for albumenoid and gelatinous substances, the authors point out that the precipitate formed in a clear solution of chondrine by acetic acid (albumenoid solutions acidulated with that acid are precipitated by solution of ferrocyanide of potassium, while gelatinous substances are not, under the same conditions, precipitated), is redissolved by the addition of solution of ferrocyanide of potassium; an excess of acetic acid re-dissolves, especially when a gentle heat or boiling temperature is applied, the precipitate first formed by that acid in a clear solution of chondrine. Tartaric acid is preferable to acetic acid for the chondrine reactions.

Gazzetta Chimica Italiana, No. 6, 1872.

This number contains the Faraday lecture, delivered by Dr. S. Cannizzaro, a report of which has already appeared in our pages.

Researches on Trichlorurated Acetal and on Tetrachlorurated Ether.—Drs. E. Paterno and G. Pisati.—After first referring to the labours of A. Wurtz and G. Vogt on this subject, the authors state that they commenced their researches by preparing, according to L. Henry's method, a larger quantity of tetrachlorurated ether. The boiling-point of that body is 189.7°; its density, referred to that of water at 4°, is at 0° 1.4379. When this ether is poured into a glass tube with alcohol, and the tube next sealed and heated in a bath of saturated brine, the result is the formation of Wurtz's and Vogt's trichlorurated acetal, a mobile transparent liquid of an agreeable odour, boiling at 204.8°; its sp. gr. at 0° is 1.2813; its formula is—

percentual composition, in 100 parts.—Carbon, 32.52; hydrogen, 4.96; chlorine, 48.05; oxygen, 14.47. This essay further treats on the researches of the first-named author on trichlorurated acetal, as obtained some time ago as a by-product of the preparation of bichloroacetal by the action of chlorine upon alcohol, the results of which experiments have been published in the *Giornale di Scienze Nat. ed Econ.*, vol. iv., 1867, and on the action of alkaline alcoholic solutions upon tetrachlorurated ether in sealed tubes exposed to a higher temperature, yielding, after purification and fractional distillation, a fluid boiling at 154.8°, having a sp. gr. at 0° of 1.3735, and consisting, in 100 parts, of—Carbon, 27.37; hydrogen, 2.85; chlorine, 60.65. This compound combines with bromine, and forms a body of which the formula is stated to be, in all probability, $CCl_2Br-CClBr.O.C_2H_5$.

Researches on the Detection of Bromine in the Presence of Urea.—Prof. G. Bizio.—This excellent essay is an addition to the author's monograph, published in 1865 (*Atti del Reale Istituto Veneto delle Scienze*). On the Influence of Urine as Modifying certain Chemical Reactions." Notwithstanding the high scientific value of this memoir, its contents are not well suited for abstraction.

La Revue Scientifique de la France et de l'Etranger,
September 14, 1872.

This number contains no original papers relating to chemistry, but is entirely devoted to the record of the proceedings of the opening of the first meeting of the French Association for the Advancement of Science. We find here *in extenso*—(1) The speech of the President, M. de Quatrefages, on "Science and Fatherland (Patrie)." (2) An excellent extempore speech by M. Fourand, the Maire of the ancient and beautiful city of Bordeaux. (3) "History of the Origin of the Association," by M. Cornu. (4) "Report on the Financial Condition," by G. Masson. (5) The reproduction of the telegram sent from Moscow, by the Russian naturalists assembled in the ancient City of the Czars for the purpose of celebrating the bicentenary of Peter the Great's birth, and remembering his merits in reference to science and civilisation in Russia, to the members of the Association at Bordeaux; from this telegram we quote the following:—"Le degré élevé que les sciences ont atteint en France est la plus belle conquête de l'humanité; puisse-t-elle prospérer et continuer au bien être général et aux liens internationaux, scientifiques humanitaires." From the reply telegram sent from Bordeaux we quote the following:—"Elle (L'Association) vous remercie donc au nom de la science que nous aimons tous et que nous voulons servir chacun dans sa sphère, chacun dans son pays, car c'est une œuvre de civilisation générale que nous poursuivons avec vous." This number also contains reports of the labours of some of the section meetings, and two lectures relating to military matters given in the general sittings. Several *savants* from foreign countries attend the meeting.

American Journal of Pharmacy, September, 1872.

This number contains no original papers relating to chemistry or collateral subjects.

The American Journal of Science and Arts, August, 1872.

In addition to several important papers relating to geology, mineralogy, engineering, and natural history, this number contains the following paper relating to chemistry:—

Estimation of Sulphur in Coal and in Organic Compounds.—W. G. Mixer.—The author's process is based upon the combustion

of the substances in oxygen, while the sulphur is condensed from the gaseous products in the form of sulphuric acid. The method of operating is fully detailed, and, from the results of experiments, it appears that this mode of determining sulphur in coal and organic compounds is more correct and expeditious than those now in use; the quantity of material operated upon may also be considerably less. Without the reproduction of the woodcut with which this paper is illustrated, the description of the apparatus is impossible.

Bulletin de la Société Chimique de Paris, August 1, 1872.

Synthesis of Parabanic Acid.—M. Ponomareff.—Urea is, according to the author, converted into parabanic acid by the action of that acid and of terchloride of phosphorus, while heat is set free, and hydrochloric acid is developed; the parabanic acid thus obtained is insoluble in alcohol. The aqueous solution yields with nitrate of silver an insoluble precipitate, readily soluble in excess of nitric acid; the formula of this silver salt is $C_4Ag_2N_2O_8$, and the formula of the free parabanic acid is $C_4H_2N_2O_8.2H_2O$ or $C_4H_2N_2O_8.H_2O$.

New Quinine Trical Process.—P. Carles.—Reserved for translation.

Memoir on Phosphoplatinic Compounds.—P. Schützenberger and E. Fontaine.—The continuation of an exhaustive monograph on this subject; it contains lengthy and complex formulae.

On Camphic Acid.—J. de Montgolfier.—The contents of this paper relate to the rectification of some errors made by Kachler as regards camphic and campholic acids. The author states that Kachler's assertion, that camphic acid is only a mixture of campholic acid and an acid resin, is not correct, and, further, refers to Berthelot's researches on this subject, published in various scientific periodicals. Lastly, reference is made to camphoronic acid, $C_{10}H_{16}O_{10}$, which can be obtained by saturating with ammonia the mother-liquor obtained in the preparation of camphoric acid.

Combinations of Dulcitol and Benzoic Acid.—G. Bouchardat.—This essay treats on hexabenzonic dulcitol, $C_{12}H_8(C_6H_5O_2)_6$, a solid crystalline body, fusing at 147°, sublimable with partial decomposition at 220°, perfectly insoluble in water and in ether, and difficultly soluble in boiling alcohol; when hexabenzonic dulcitol is suddenly heated to 200°, and then cooled, it becomes an amorphous mass, entirely soluble in ether; it soon, however, crystallises. Tetrabenzonic dulcitol—

is also a solid resin-like body, insoluble in water, and nearly so in alcohol; this substance is sublimable without decomposition, and fuses at 150°.

Archives Néerlandaises des Sciences Exactes et Naturelles, Vol. vii.,
No. 1, 1872.

In addition to purely mathematical and algebraical papers, this number contains the following original memoirs relating to chemistry and collateral subjects:—

Action of Light upon Chlorophyll.—E. Gerland.—This exhaustive essay treats on the combined effect of light and oxygen upon chlorophyll. Among the conclusions drawn by the author we quote the following:—In the presence of air and light the molecules of chlorophyll are submitted to the action of two forces, which tend to alter them, viz., the chemical action of oxygen and the action of light; but, in order to affect any alteration, the joint action of the two is required, as in the dark, unless oxygen is also present, no alteration of the chlorophyll takes place. When a solution of chlorophyll is exposed to the action of air and light, the oxygen combines with the pigment, which thus becomes modified; and when the intensity of the light is sufficiently strong, this action of the oxygen is interrupted, and decoloration of the chlorophyll ensues. If, however, the intensity of the light is weak, the oxidation proceeds, and the pigment is entirely converted into modified chlorophyll. A large portion of this essay is devoted to spectroscopical researches on chlorophyll.

Crystallites, and Crystallogenic Studies.—H. Vogelsang.—This is the continuation of a monograph on this subject, illustrated by engravings exhibiting crystalline substances seen by the microscope.

Agronomic Systems of the Netherlands.—W. C. H. Staring.—This memoir contains information on the rotation of crops, and on the extent of cultivated and uncultivated land, including lakes, marsh ground, and moors, in the Netherlands, and on the divers systems of agriculture. Nearly one-fifth of the entire surface of the kingdom is entirely unfit for cultivation, while more than another one-fifth is meadow land; 28,600 hectares are market gardeners' land; 20,000 hectares are orchards; 19,000 are cultivated with tobacco; 14,000 with hemp; 150 with hops (only in one district); and 200 hectares are specially devoted to the cultivation of bulbs of tulips, hyacinths, &c. The total surface of the kingdom is here stated to be 3,289,000 hectares.

Les Mondes, September 5 and 12, 1872.

These numbers contain no original matter or communications relating to chemistry and collateral subjects.

Revue Universelle des Mines, de la Métallurgie, des Travaux Publics, des Sciences et des Arts Appliqués à l'Industrie, May, 1872.

This number contains no original papers relating to chemistry.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents
34, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2454. W. Ferrie, Airdrie, Lanarkshire, N.B., "Improvements in connection with furnaces for smelting iron."—Petition recorded August 17, 1872.
2491. C. F. Seville, Paris, France, "Improvements in the composition known as 'schisto-asphaltic and bituminous beton' and novel applications thereof, together with improved machinery or apparatus in connection therewith."
2497. J. R. Roper and A. Alexander, Sheffield, Yorkshire, "Improvements in the treatment of iron and manufacture of steel."—Petitions recorded August 22, 1872.
2515. R. Goodall, Armley, Leeds, Yorkshire, "An improved means or method of, and apparatus for, clarifying impure or waste water from fulling mills, scouring mills or scouring processes, dye-houses, sewage, and other impure waters."—Petition recorded August 24, 1872.
2527. C. Frickinger, Berlin, Prussia, "Improvements in the manufacture of malleable iron and in the furnaces employed therein."
2529. H. A. Duferré, Paris, France, "An improved mode of preserving fruit."—A communication from F. Sacc, Neuchatel, Switzerland.—Petitions recorded August 26, 1872.
2545. C. Morfit, Baltimore, Md., U.S.A., "Improvements in vats or vessels for the various chemical and manufacturing operations which involve the use of acids."—Petition recorded August 27, 1872.

INVENTION PROTECTED BY THE DEPOSIT OF COMPLETE SPECIFICATION.

2572. W. R. Lake, Southampton Buildings, London, "Improved compounds, chiefly designed for coating ships' bottoms."—A communication from J. H. Bloodgood, New York, U.S.A.—Petition recorded August 29, 1872.

NOTICES TO PROCEED.

2095. B. Todd, Newcastle-upon-Tyne, "Improvements in the treatment of gases and fumes."—Petition recorded July 5, 1872.
2417. F. D. Blyth, Fenchurch Street, London, and A. G. Southby, New Inn, Middlesex, "Improvements in the process and apparatus for heating wood for the manufacture of pulp for paper."—Petition recorded August 14, 1872.
2431. T. Routledge, Ford Works, near Sunderland, "Improvements in treating fibrous substances for textile purposes, and for the manufacture of paper stock."
2443. W. R. Lake, Southampton Buildings, London, "Improvements in puddling furnaces."—A communication from G. E. Harding, New York, U.S.A.—Petitions recorded August 15, 1872.

PATENTS SEALED.

705. A. F. Andrews, New Haven, Conn., U.S.A., "Improvements in the process of making malleable cast-iron and in apparatus therefor."
715. J. Garneri, Gracechurch Street, London, "A new system or process for the production and decomposition of anhydrous chlorides, and apparatus for those purposes."—Dated March 8, 1872.
958. C. D. Abel, Southampton Buildings, Middlesex, "An improved process for the preparation of acid phosphate or superphosphate of lime."—A communication from G. Ville, Paris, France.—Dated April 1, 1872.
1509. J. A. Froitzheim, Cologne, Prussia, "Improved manufacture of explosive compounds."—Dated May 17, 1872.
1951. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in preserving butter and other fatty matters, and in the apparatus or means employed therein."—A communication from Bnault and Company, Paris, France.—Dated June 28, 1872.
2029. B. J. B. Mills, Southampton Buildings, London, "Improvements in sizing paper, paper pulp, cotton, linen, and other fabrics and materials, and in materials to be employed therefor."—A communication from J. MacDorian, East Brandywine, Penn., U.S.A.—Dated July 4, 1872.
2119. W. R. Lake, Southampton Buildings, London, "An improved gypsum cement."—A communication from E. F. A. Schott, Seesen, Germany.—Dated July 13, 1872.

FOREIGN PATENTS.

UNITED STATES OF AMERICA.

TO CORRESPONDENTS.

- A. M. Edwards, Newark, N.J.—We will bear it in mind.
- H. Townsend.—The work will not be completed for some time to come.
- Prof. R. V. Tuson.—Unfortunately your communication did not arrive until we had gone to press.
- W. F. D.—We are sorry we did not receive the information earlier. An advertisement would be beneficial.
- H. B. Yardley.—As far as we know no such table is published, but it is easy to calculate from the tables of specific gravity of acids.
- Sydney Gibbons, Melbourne.—Received with thanks.
- Dr. J. Emerson Reynolds.—We are obliged for your communication.

THE CHEMICAL NEWS.

VOL. XXVI. No. 670.

THE ALLEGED CONVERSION OF ALKALINE SULPHATES INTO CHLORIDES BY IGNITION WITH AMMONIUM CHLORIDE.

By EDWARD NICHOLSON, F.C.S.,

Assistant Surgeon, Royal Artillery; Analyst of Waters, Madras Presidency.

AN error, occurring originally in Fresenius, and copied from it into other analytical handbooks, has come to my notice in a rather peculiar manner. A new scheme (the third) for the analysis of potable waters has lately been inflicted, by authority, on India; and in a local medical journal I criticised it rather severely, though not more so than it deserved, as it is a mere patchwork of processes, many of them good, but picked out of books and put together with little evidence of either practical chemical knowledge or of Indian experience. One of the processes I criticised was the following; it occurs in the process for the determination of alkalis:—

"Add some chloride of ammonium (to convert sulphate of sodium or potassium into the chloride), evaporate, ignite, and weigh the residual chloride of sodium and potassium. If the water contain only a small proportion of sulphuric acid, the addition of the chloride of ammonium will suffice for the conversion of the sulphates into chlorides; but if the proportion of sulphuric acid is large, it is necessary to add at once, before the addition of the milk of lime, a quantity of chloride of barium equivalent to the known amount of the sulphuric acid."

I pointed out that the reaction indicated was an impossible one, and that there was not the slightest ground, *in fact*, for the assertion that sulphuric acid could be thus expelled.

Rejoinders followed, more remarkable for faith in textbooks than for evidence of profit by their teachings; it was pointed out that the process, being copied from Fresenius, must be quite correct. One anonymous representative of Indian professorial chemistry declared that he would rather "go to hell with Fresenius than to heaven with Mr. Nicholson." The author of the scheme declared, more politely, but no less strongly, that he and the authorities were right; he regretted the consequences which my temerity will bring down on me. An apothecary, who is officiating as assistant to the Madras Professor of Chemistry, alone had the happy thought to try the experiment; and he proved most satisfactorily to himself that Fresenius is right, provided that not more than 1 milligramme of alkaline sulphate is operated on; beyond that quantity the spell refuses to work, and the conversion is incomplete.

In consequence of this little episode, I proceeded to examine how far it is possible for ammonium chloride to effect any permanent change in alkaline sulphates.

The following experiments were made with salts of ascertained purity. In each case the mixture was dissolved in a little water, and the solution evaporated down on the water-bath. The ignition was made as rapidly as could be without incurring danger of decrepitation.

(1). 0.0967 grm. of sodium sulphate, ignited with 0.2330 grm. of ammonium chloride. Weight of residue unaffected to within 0.0001 grm. Dissolved in 5 c.c. of water, it gave less than 0.0002 grm. of chlorine. Formation of sodium chloride equal to about 3 parts in 1000.

(2). 0.022 grm. of sodium sulphate ignited twice, each time with 0.010 grm. of ammonium chloride. The residue, dissolved in 2 c.c. of water in 1 c.c. of the amount of sul-

phate had undergone no perceptible alteration; in the other, silver nitrate produced a slight opalescence, estimated to be equal to that produced in 1 c.c. of a water containing 0.03 grm. per litre of sodium chloride. As nearly as could be estimated on such a minute quantity, the amount of chloride formed amounted to 30 parts per 1000.

(3). 0.010 grm. of sodium sulphate ignited twice; the first time with 0.065 grm., the second time with 0.130 grm. of ammonium chloride. The residue gave 0.0001 grm. of sodium chloride. Conversion equal to 10 parts per 1000.

(4). 0.0324 grm. of sodium sulphate, ignited with 0.0500 grm. of sodium chloride and 0.0840 grm. of ammonium chloride. This experiment would correspond to that performed in the treatment of a litre of ordinary potable water. The loss of weight after ignition was 0.0010 grm.; but this was rather uncertain, owing to the difficulty in weighing sodium chloride accurately in the very damp climate where the experiment was made. Sulphuric acid was determined in the residue, also in 0.0324 grm. of the original sodium sulphate. The results were—

	BaSO ₄ .	SO ₄ .
Original salt	0.0539 grm.	= 0.0222 grm.
Residue of ignition 0.0537 "	"	= 0.0221 "
Theory	—	= 0.0219 grm.

I think these experiments show that, even with very small quantities, there is practically no change effected in the process under discussion. The very partial reaction that does take place is of no use in analysis; the process is an ineffectual attempt at forcible reversion of the ordinary reaction, by bringing a large excess of ammonium chloride to bear on the sulphate. Evaporation and ignition with ammonium chloride only affect the nitrates, carbonates, and silicates present in water, but ammonium sulphate converts all chlorides, nitrates, &c., into sulphates; in fact, sulphuric acid acts just as effectually when guarded* with ammonia as when free. I am rather surprised at seeing this erroneous statement persistent in successive editions of Fresenius.

I intend to investigate the statical points connected with the reaction of ammoniacal salts on alkaline sulphates and chlorides; in the meantime, I think it advisable to draw attention to the error occurring in the handbooks of analysis.

Vizagapatam, June 18, 1872.

ON THE OCCURRENCE OF NATIVE SULPHURIC ACID IN EASTERN TEXAS.

By J. W. MALLETT, Ph.D., M.D.,

Professor of Pure and Applied Chemistry, University of Virginia.

Not far from the Gulf of Mexico, and within twenty-five or thirty miles to the westward of the Neches river, there occur at several localities—in some instances in the woods, in others in the midst of open prairie—small drainage-wells and shallow pools of water strongly sour to the taste. This sourness is due to the presence of free sulphuric acid, which is accompanied by various salts, especially aluminium and iron sulphates. At most of these points gases are continually escaping (hydrogen sulphide, marsh gas, and carbonic anhydride), the bubbles burning readily on the application of a light.

At the bottom of the water in some instances, as at one point where, by means of an artificial bank, a pond has been formed of some 250 feet in diameter, known locally as the "sour lake," an earthy crust with intermingled

* I use the term "guarded," as it expresses the effect very well. Nitrous waters may be evaporated down with ammonium sulphate without fear of platinum vessels being attacked, as would be the case in presence of free sulphuric or hydrochloric acid.

† Read before the British Association, Brighton Meeting, Section B

ree sulphur is observable. A thick, tarry variety of petroleum is found oozing from the surrounding soil, occasionally to such an extent that sods taken up with a spade are set on fire and used to give light in the open air at night.

At a point in Louisiana some fifty or sixty miles further East, where, however, the acid water does not occur, though combustible gas and petroleum are met with on the surface, a most remarkable bed of native sulphur, 100 feet in thickness, has been reached at the depth of 450 feet by boring, and a shaft is being at present sunk for its exploitation. This large mass of native sulphur is more or less mingled with calcium carbonate, and underlaid by gypsum. The circumstances connected with the occurrence together in this region of combustible gases, petroleum, sulphur, sulphuric acid, and gypsum are of great interest in relation to the mineral history of native sulphur.

The sulphuric acid water, which seems to be probably altogether of superficial origin, is worthy of notice from the unusual strength occasionally attained. The water varies very much at the different localities and at different times. In one instance, a specimen examined by Dr. Mallet contained no less than 5.290 grms. of free sulphuric acid (H_2SO_4) to the litre, or 370 grs. to the imperial gallon, this exceeding any amount hitherto reported from other localities, unless the acid spring of the Paramor de Ruiz, in New Granada, be an exception, examined by Lewy, who does not state precisely how much of the very large quantity of sulphuric acid found is uncombined with bases. The water of the Rio Vinagre, flowing from the volcano of Purace in the Andes of Popayan, as described by Humboldt and Boussingault, contains only 1.11 of free sulphuric acid (SO_3 ?) in 1000 parts of the water, with 0.91 of hydrochloric acid.

It is said, on the authority of Confederate officers serving West of the Mississippi, that during the blockade of Southern ports the galvanic batteries of telegraph offices in Texas and Western Louisiana were worked with this native sulphuric acid.

NOTE ON A CITRATE OF BARIUM.

By E. SONSTADT.

CHEMICAL text-books describe a class of citrates to which the formula $C_{12}H_{11}M_5O_{14}$ is assigned, and which might be called di-tri-metallic citrates, since the formula may be obtained by addition of the formulæ of a di- and of a tri-metallic salt. As this formula differs but little from the formula of a citrate shown, in my paper on "The Oxidating Power of Iodide of Potassium," to be chemically neutral in reference to a liquid there described, and in which the number of atoms of metal are to the number of atoms of hydrogen as 1:2; it occurred to me as probable that the formula given in the books may have been incorrectly given to salts really constituted according to the formula $C_6H_5M_3O_7$, or the double of that, $C_{12}H_{10}M_6O_{14}$. Since salts of this kind must be prepared for analysis by drying at a temperature not far removed from that at which they begin to decompose, a doubt being thus introduced as to the perfectness of their preparation, it seemed useless to attempt by analysis to establish entirely beyond doubt which of the two formulæ is correct,—especially as the percentage of metal in the two cases respectively can differ but very little in respect to the total weight of salts taken for analysis. But the formula in which the proportion of metal to hydrogen is given as 5:11, is satisfied by adding one atom of citric acid to five atoms of a tri-metallic citrate; whereas the formula requiring 1:2 is satisfied by adding one atom of citric acid to eight atoms of a tri-metallic citrate,—a difference wide enough to admit of very satisfactory experiments.

Eight parts by weight of citric acid were exactly

saturated by solution of carbonate of sodium, so that the reaction was neutral to litmus-paper. 1 part of citric acid was dissolved in the liquid, solution of chloride of barium added in excess, and then about twice the volume of the liquid of alcohol. The liquid, filtered after a while, was neutral to test-paper, or had only a scarcely recognisable acid reaction. Hence the precipitate of barium citrate formed must have contained the whole of the citric acid employed, and therefore the barium was to the hydrogen in the citrate as 1:2. In other experiments, when a larger proportion of citric acid to tri-metallic citrate was used, the alcoholic filtrate was always strongly acid.

Quantitative experiments were now made, in which 1 part of citric acid was taken to 5 parts of citric acid for neutralisation; and, in one case, 3 atoms acid to 10 atoms tri-metallic citrate. Weighed quantities of chloride of barium, adjusted to give neither excess nor deficiency, were added; and the acid in the alcoholic filtrates was estimated by a standard alkaline solution. In the first three experiments, the amount of citric acid in the precipitates (over what was included as tri-metallic citrate) was also estimated, by boiling these precipitates with sulphate of potassium in excess, and neutralising the solution by the standard alkaline solution. As the sum of acid found in filtrates and precipitates agreed nearly with the total excess of acid over what was needful to form tri-metallic citrates, in the remainder of the experiments the acid in the filtrate only was directly observed, that carried down in the precipitates being calculated.

In four experiments, in which 5 parts of citric acid were neutralised by soda, 1 part citric acid added, and then chloride of barium in equivalent proportion, and alcohol, the acid in the filtrate to that in the precipitate were—(1) 12:28; (2) 12:28; (3) 12:28; (4) 15:25, but in this (4) the experiment was varied by adding the chloride barium to the citrate formed by neutralising the 5 parts citric acid taken, by soda, then alcohol, and lastly, the reserved part of citric acid. In experiment (5) 3 parts citric acid were used to 10 parts acid neutralised by soda; or one-third more citric acid than necessary to give the salt $C_{12}H_{11}M_5O_{14}$. The proportion formed in this case of acid in filtrate to acid in precipitate was 28:32. If the citrate of barium formed in these experiments had the composition $C_{12}H_{11}M_5O_{14}$ there could, in experiments (1) to (4), have remained no acid in the filtrates. In experiment (5), it would have been as 20:40. The formula $C_{12}H_{10}M_6O_{14}$ requires the proportion of acid in filtrates, and precipitates in experiments (1) to (4) to be as 3:5, or as 15:25; and in experiment (5), as 35:25. In each experiment, therefore (except in (4) where the proportion agrees with theory), a small proportion of acid over the proportion required by theory was carried down, and the proportion thus carried down was largest in experiment (5), where the citric acid was used in largest excess. It might be supposed that possibly a di-tri-metallic barium citrate may have been formed in these experiments, and that the acid found in the filtrates was due to the solubility of such barium salt in alcohol. In such case, the proportion of barium in the filtrates should be proportional to the acid found in them. In experiment (5), where, evidently if this is so, a larger proportion of barium should be found in the filtrate than in the other experiments, the barium was quantitatively determined, and found a little under 2 per cent of the barium in the precipitate. It seems impossible, therefore, to deduce any other conclusion from these experiments, than that the formula $C_{12}H_{10}M_6O_{14}$ (and not $C_{12}H_{11}M_5O_{14}$), is correct for the salt in question.

I endeavoured to obtain a corresponding ammonium salt, by drying up tri-metallic ammonium citrate on the water-bath. Ammonia, however, was continuously given off, and the glutinous mass remaining, still smelling of ammonia, was found to have parted with nearly half (six-thirteenths) of the ammonia originally contained in the salt. The behaviour of ammonium citrate at the tem-

perature of boiling water, is therefore comparable to that of ammonium phosphate at a much higher temperature.

When 8 parts citric acid are saturated with soda, and 1 part acid added, a crystallised salt is obtained by long standing of the concentrated liquid, with difficulty. The crystals consist of tri-metallic citrate. It does not appear, therefore, that the salt $C_{12}H_{10}Na_3O_{14}$ is crystallisable. But alcohol precipitates from a solution of this salt a dense fluid, and the supernatant liquid is only slightly acid to test-paper.

As the existence of a class of salts containing fractional atoms of base appears inconsistent with the etymological meaning of the word "atom," and opposed to the most commonly received "atomic theory," I propose to carry these researches further as I may have opportunity. Should other tri-atomic acids than citric acid be found to give corresponding salts, the discussion of the theoretical bearings of the existence of such salts will be much simplified, because they can then be viewed apart from the special constitution of a single organic acid which is supposed by some to be derived from a triple molecule.

CHANGES PRODUCED IN THE GLOBULES OF THE BLOOD AND THEIR RELATION TO SECRETIONS.

M. RITTER, of Strasburg, in a recent thesis to the Paris Faculty of Sciences, discusses this question; having investigated the action of the following substances on the blood globules, and correlatively on the excretal humours, viz., oxygen, protoxide of nitrogen, oxide of carbon, compounds of antimony and of arsenic, phosphorus, and biliary acids. We give an abstract of his results.

Action of Oxygen.—Since the discovery of oxygen, its action on the blood and tissues has been studied by various physiologists; to whose works M. Ritter makes reference. MM. Demarquay and Leconte observed that animals could breathe pure oxygen a long time without inconvenience, and that the pulse was sometimes accelerated, and a feeling of comfort produced. Allen and Pepys inferred from experiment that the quantity of carbonic acid excreted increased with oxygenation of the air: but this has been denied. M. Ritter studied especially the influence of oxygen on urinary excretions. He submitted himself to a fixed daily diet, producing a certain quantity of urine, and he compared the urine of days on which he absorbed pure oxygen with that of other days on which he did not do so. In the former case he inhaled 25 to 30 litres of oxygen, inspiring the gas gently from a gasometer, as when one smokes. From analysis of the urine obtained under these conditions, M. Ritter found the acidity increased, the quantity of nitrogen and of urea diminished, the uric acid diminished, and the ammoniacal salts increased considerably. The products were those of advanced oxidation.

This urine obtained after inhalation of oxygen, underwent acid fermentation very quickly, and remained acid for a long time, sometimes not becoming alkaline till after two months; and he asks if therapeutical science might not take advantage of this fact in affections in which the urine has a pronounced tendency to ammoniacal fermentation, and if inhalation of oxygen might not happily modify this morbid property.

M. Ritter did not experience the feeling of comfort referred to by other physiologists; his pulse became less rapid, but fuller, the legs felt somewhat benumbed.

Comparing the urine produced in states of repose and in states of muscular activity, M. Ritter found, that after a state of complete repose, walking produces phenomena of oxidation different from those observed after inhalation of pure oxygen. The quantity of nitrogen eliminated in the urine is increased instead of diminished, and the proportion of urea to uric acid increases nearly one-half.

Action of Protoxide of Nitrogen.—M. Ritter obtained the gas from nitrate of ammonia in a retort placed in an oil-bath heated by gas, so that the temperature of the salt was raised to $+230^{\circ}$; the gas being produced at the rate of about 6 litres per hour. It traversed tubes containing litmus, potash, ferrous sulphate, and pyrogallate of potash, and was collected over water from which the air had been expelled by boiling. It could thus be had very pure.

According to M. Ritter, protoxide of nitrogen is a very poisonous gas. For example, a pigeon placed in a receiver containing 80 per cent of the protoxide, died immediately. When defibrinated blood is agitated with protoxide of nitrogen it is reddened as by oxygen; but after some time it becomes bluish-red. M. Ritter considers that the protoxide is first absorbed by the globules and then expelled by the oxygen of the serum.

He experimented with pigeons, rabbits, and frogs, and found that protoxide of nitrogen, mixed with its own volume of air, always diminishes the oxidation, and cannot sustain life. The inhalation of a volume of air containing $\frac{1}{10}$ th of protoxide diminishes considerably the quantity of carbonic acid, but without stopping the respiration. If this proportion is reduced to $\frac{1}{20}$ th, the quantity of carbonic acid does not sensibly alter. Thus we see that in 50 per cent of protoxide of nitrogen life is impossible; in 5 per cent it is not at all deranged.

Next as to the effect on urinal excretion, M. Ritter drank water saturated with the protoxide, and he found that all the immediate principles of urine were increased; there was diuresis. When the absorption of the gas was continued, the proportion of uric acid to urea rose considerably.

Action of Oxide of Carbon.—M. Bernard has shown that blood mixed with oxide of carbon loses its gases, and especially its oxygen, in a very short time. The oxide prevents hæmatosis, and kills the blood. Examining the effects of this substance absorbed in doses which were not toxic, M. Ritter found diminished oxidation, and the urine to have become albuminous, containing both albumen and albuminose.

Action of Compounds of Antimony.—M. Ritter employed the emetic and sulphuret of antimony, studying their effects on men, rabbits, dogs, and geese. Having taken, for some time, 5 milligrammes of emetic daily, he did not obtain very distinct results on analysis of the urine, but it appeared that the principles of oxidation were somewhat diminished. The same is to be said of dogs, which were given 15 and 20 milligrammes of emetic daily. Their urine did not contain morbid principles.

In some parts of Germany, glass of antimony is mixed with the paste given to geese, with the view of fattening them. M. Ritter wished to test the value of this idea, and found that under the influence of 5 and 10 centigrammes of sulphuret of antimony daily, the sugar and fat of a goose increased very little. There was no alteration in the globules. With stronger doses, the quantity of fat did not further increase. The blood contained less carbonic acid and oxygen.

Action of Arsenious Acid.—The result of experiments, on geese chiefly (the dose of arsenic ranging from 5 to 20 milligrammes) was that small doses produced a considerably greater formation of fat, while strong doses caused emaciation. (M. Ritter believes the custom of giving geese glass of antimony to fatten them, is really based on the fattening effects of arsenic, which glass of antimony always contains). The globules of the blood were only altered by very strong doses. Crystals of hæmoglobin were sometimes met with. In this case the urine was icteric and albuminous. Glucose increased in the plasma. M. Ritter adds, that in his experiments with men, he never met with the colouring and *embonpoint* which are said to result from arsenicophagy.

Action of Phosphorus.—Two milligrammes were given daily to dogs; in 10 or 12 days they became icterically diseased, and were then killed. The urine contained bile and albumen, and was less acid and less rich in urea.

The blood contained a large proportion of fatty matter and of cholesterine. The globules were viscous, and a little deformed. Other dogs, to which 10 milligrammes were given daily, were killed after a week. The blood was violet, and crystallised under the objective of a microscope, though the crystals were rare. The deformed globules had a raspberry appearance. All the organs showed fatty degeneration. The urine contained albumen, hæmoglobin, and biliary pigments, and was alkaline. Geese were very sensitive to the action of phosphorus, and could only bear it in very small doses. The general result was, that deposits of fat in the liver and various members were notably favoured by small doses of phosphorus, but strong doses had no such action.

Action of Biliary Acids.—In some cases, M. Ritter bound the choledochus, and, in others, injected salts of biliary acid into the veins. In every case the blood was greatly changed, showing crystals of hæmoglobin, and divided globules. It became richer in fat and cholesterine; the temperature fell. Analysis of the urine gave the same results as in the case of phosphorus. Salts of the bile acted more quickly and energetically than the phosphorus compounds. The colouring matters of the bile, on the other hand, had no toxic properties.

M. Ritter's *resumé* of results is briefly as follows:—When animals are subjected to the action of substances which greatly alter the blood globules (as compounds of antimony, arsenic, and phosphorus), crystals of hæmoglobin appear in the deformed globules; the blood is anemic, the albumen in the globules diminishes; the fibrin increases, the proportion of gas diminishes, glucose generally, but not always, increases; fatty matters and cholesterine always increase; and the variations in these correspond to the dose of the poison and the alteration in the globules. The composition of the urine varies also; the entire quantity of nitrogen and urea diminishes; the acidity diminishes and gives place to alkalinity; uric acid always increases, when the globules are greatly changed. The urine contains abnormal principles, which are most frequently colouring matters of the bile, albumen, and sometimes hæmoglobin. The compounds whose action we are considering promote formation and deposition of fat, but only when administered in certain doses.

A. B. M.

DETECTION OF BISMUTH BY THE BLOWPIPE, IN THE PRESENCE OF LEAD AND ANTIMONY.

By H. B. CORNWALL, E.M.

BISMUTH may be readily detected in the presence of antimony by the blowpipe. So likewise when with lead, by the salt of phosphorus bead and tin, even if only 0.05 per cent of teroxide of bismuth is present in otherwise pure oxide of lead. Antimony, however, yields a similar reaction with salt of phosphorus, and it has always been necessary to resort to the wet way to settle, with certainty, the presence of little bismuth with much lead and antimony.

Von Kobell's observations (*Journal für praktische Chemie*, No. 10) on the behaviour of bismuth compounds with a mixture of equal parts of iodide of potassium and sulphur, noticed in the *CHEMICAL NEWS*, vol. xxiv., p. 110, suggested to the writer the use of this reaction in mixtures of the three metals, or their compounds. According to von Kobell, any bismuth compound, treated B. B. with the iodide mixture on a large coal, affords a beautiful and very characteristic red coat, at quite a distance from the assay. The writer has always obtained the reaction by employing teroxide of bismuth and iodide of potassium, entirely free from sulphur, but the sulphur adds exceedingly to the delicacy of the test.

With the view above stated, the writer made the

following experiments, by heating on coal with the iodide mixture, different compounds:—

(1). Teroxide of bismuth. The red bismuth coat was beautifully formed.

(2). Protoxide of lead, free from bismuth. A copious and bright yellow coat was formed, as far from the assay as the bismuth coat.

(3). Oxide of lead, with 10 per cent teroxide of bismuth. At first a slight, but marked, red bismuth coat, quickly covered by the lead coat; which, however, had a pale orange tint, showing bismuth.

(4). Oxide of lead with 5 per cent teroxide of bismuth. A yellow coat, in no way distinguishable from that in Expt. 2. By heating a fresh portion of the oxide of lead and iodide mixture and letting the fumes condense, for a moment only, on the cold yellow coat already formed, this assumed a dark orange shade, but the reaction was far less characteristic than that obtained in Expt. 7.

(5). Oxide of lead with 1 per cent teroxide of bismuth. A coat perfectly resembling that in Expt. 2.

To increase the delicacy of the test, experiments were made in open tubes, 4 in. long, and not less than $\frac{1}{4}$ in. wide, over a Bunsen gas burner. A spirit-lamp answers as well. The iodide mixture now used contained 5 parts sulphur and 1 part iodide of potassium, by weight; and about equal volumes of this and of the metallic oxides were used. The iodide and sulphur mixture of equal parts no longer served the purpose.

(6). Oxide of lead. First, part of the sulphur sublimed and condensed above the assay, its heavy vapours also burning at the lower end of the tube. Then, copious yellow fumes passed through the tube, and an abundant sublimate condensed, which commenced about one-third of an inch above the assay, and when quite cold had a pure, bright yellow colour.

(7). Oxide of lead with 1 per cent teroxide of bismuth. The same phenomena as in Expt. 6, but one-third of an inch above its lower edge the yellow sublimate was replaced by a broad and distinctly red ring of the bismuth sublimate.

(8). Oxide of lead with $\frac{1}{4}$ per cent teroxide of bismuth. As in Expt. 7; the bismuth sublimate, however, being rather orange-red, but so distinctly marked as to leave no doubt that even a less proportion of bismuth could have been certainly detected.

(9). 50 parts oxide of lead, 50 parts teroxide of antimony, and 1 part teroxide of bismuth. The white antimonial sublimate entirely concealed the bismuth reaction. To obviate this the mixture of the three oxides was mixed with an equal volume of sulphur and treated B. B. in a deep cavity on coal, with the blue flame, for a few moments. The resulting fused sulphides were removed to a flat coal, and treated alternately with the O. F. and R. F. until the antimonial fumes had nearly ceased, and an impure blue lead flame appeared. The residue was powdered, and a portion of it treated with iodide mixture on coal. No bismuth was detected. The other portion was treated as before in the open tube, when a distinct bismuth sublimate formed, about one-third of an inch above the lower edge of the yellow sublimate. The experiment was repeated with like success on equal parts of oxides of lead and antimony containing $\frac{1}{4}$ per cent and $\frac{1}{4}$ per cent of teroxide of bismuth; and, as was to be expected, the bismuth reaction was more distinct than when the bismuth was present with lead only.

Therefore, to detect oxide of bismuth in mixtures of oxides of lead and antimony, follow the method given in Expt. 9, if there is not any decisive result obtained by the test on coal. If sulphides are under treatment, remove the excess of antimony on coal, as above.

Care must be taken not to confound with the bismuth sublimate a sublimate of iodine, which may condense on the upper part of the tube, but at a greater distance from the assay.—*American Chemist*.

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.*

By Dr. F. CRACE CALVERT, F.R.S.

(Continued from p. 142).

Annatto is the pulpy part of the seeds of the *Bixa orcellana*, which grows in South America. It is imported into this country from Mexico, Brazil, the Antilles, and especially from Cayenne, in masses covered with leaves, and varying in weight from 5 to 20 lbs. It is also imported in casks, weighing 4 or 5 cwt., as a homogeneous paste of the consistency of butter, and often having a repulsive odour of urine, which, it is stated, is added by those who store it, to keep it moist and to impart to it a richer hue.

At Cayenne, when the fruit of the *bixa* is ripe, it is gathered, coarsely crushed, and thrown into water, where it remains for several weeks. By this means the pulpy matter is separated from the kernel. It is next strained through a coarse cloth, and the colouring-matter gradually subsides. It is then collected, and the excess of water evaporated, until it assumes a pasty state, when it is exposed to the atmosphere in the shade until sufficiently dry to be shipped. The powder so prepared, and especially at Cayenne, is comparatively inferior, owing to the mass fermenting and producing matters which prove injurious in the drying process. The following analysis may be taken as the average composition of such qualities of annatto:—

Water	72.25
Leaves	3.85
Starch, mucilage, woody fibre ..	18.30
Colouring-matter.. .. .	5.60

100.00

Some thirty years ago, a M. du Montel introduced at Cayenne some marked improvements in the manufacture of annatto. He suppressed the crushing of the seeds, separated the colouring-matter by water, and prevented the fermentation by the addition of some chemical fluid. By this means he obtained annatto in a minute state of division, and having a very beautiful red colour, which is imported into this country in the form of small tablets, which are much used for colouring cheese.

An alkaline solution of annatto gives an orange precipitate with acids, alum, or sulphate of protoxide of iron, a yellowish brown precipitate with salts of copper, and a lemon-coloured precipitate with chloride of tin.

The colouring matters of annatto have been studied by MM. Chevreul, Kerndt, and Bolley. It contains two colouring matters, one a yellow, which is soluble in water and alcohol, but insoluble in ether, and which gives a yellow colour to cloth mordanted with alum. It has received the name *orelline*, and its formula is $C_{12}H_{22}O$. According to Kerndt's statement, however, it is only a product of the decomposition of the second colouring-matter, the real colour-giving principle of annatto being *bixine*, $C_7H_6O_2$. Bolley proposes the following method to obtain *bixine*:—The best quality of annatto from Cayenne, after having been washed and dried, is boiled with concentrated alcohol; the alcoholic solution is evaporated to dryness, and placed to digest with ether, which dissolves a part of the residue, leaving a bright red powder, insoluble in water, but soluble in soap and alkalies, to which it imparts an orange tint, and yields a dark blue colour with sulphuric acid.

The use of annatto in print and dye works is rather limited, its chief employment being to modify the shades of other dyes, such as certain tints of yellow produced by fustic or quercitron. It is also used to give a bottom to cotton before it is dyed with safflower or cochineal.

* The Cantor Lectures, delivered before the Society of Arts. Re-vised and communicated by the Author.

In the production of oranges in steam styles, annatto is now entirely superseded by *aurine*, a colour derived from carbolic acid. It is still often used in dyeing a low class of cotton yarns. The yarn is dipped in an alkaline solution of annatto, and then passed through a weak solution of oil of vitriol which precipitates the *bixine* in the fibre. It is then only necessary to wash the cotton to complete the operation. If an orange-yellow tint is required, the cotton is previously mordanted with tin.

Ilixanthine is the name given to the pale primrose yellow crystals obtained by Dr. Schunck from the leaves of the *Polygonum fagopyrum*, or common buckwheat. This body, to which he gives the formula $C_{30}H_{20}O_{20}$, is only sparingly soluble in hot and cold water, but more soluble in alcohol. Strong sulphuric acid changes its colour to a deep yellow without decomposition. It yields on a piece of calico mordanted with alumina a dark yellow colour, with tin a light yellow, and with oxide of iron various shades of yellowish brown, according to the strength of the mordant employed.

Lo-kao.—In 1851 and in 1852, public attention was drawn by several English gentlemen to samples of a green colouring matter imported from China; in 1853, Messrs. Guinon, of Lyons, imported such quantities as to enable them to dye silk for the requirements of the trade. The silks so dyed were known by the names *Vert-Venus*, *Vert-Azof*, and *Vert-Lumiere*, and were especially admired from their remaining green in artificial light. They are not, however, now produced, as the colours were unstable, and Messrs. Guinon, Mamas, and Bonnet, found that they could produce greens which maintain their colour in artificial light by first dyeing their silks in Prussian-blue, and then immersing them in an acidulated bath of picric acid. It is interesting to observe that, if indigo be substituted for Prussian-blue, the colour appears blue by artificial light.

Lo-kao is the only substance with which I am acquainted, capable, with proper reagents, of producing the seven colours of the spectrum.

M. Charvin, of Lyons, obtained *lo-kao* from a weed indigenous to Europe—the *Rhamnus catharticus*, and received for his discovery a gold medal, worth 6000 francs, from the Chamber of Commerce of Lyons. All these *vert-lumieres* are, however, now replaced by the brilliant greens obtained from aniline.

Tannin matters can be divided into two classes, those which give a blue-black precipitate with persalts of iron, such as gall-nuts, sumach, divi-divi, myrobalans, and valonia, and those which give a green colouration with persalts of iron, such as catechu, gambier, gum kino, and elder, larch, and willow barks.

The first class are characterised by containing two acids, which have received the names of tannic and gallic acids.

Tannic acid, which is the all-important compound in this class of substances, was extracted some years ago by the following simple process, devised by M. Pelouze. It consists in treating in a displacement apparatus, coarsely ground gall-nuts with ether which has been previously well shaken with water (during this process it has taken up one-tenth of its weight of the water). The ethereal solution, on being allowed to stand, separates into two layers, the upper one being nearly pure ether, and the lower one being an aqueous syrupy solution of tannin, which only requires to be evaporated in a water-bath to obtain the tannic acid as a pale yellow spongy mass, inodorous, and having a most astringent taste. As is seen by the process of extraction, it is soluble in water, but insoluble in ether. It is soluble in alcohol. It is characterised by giving a blue-black precipitate with persalts of iron, but none with protosalts, and a white precipitate with tartar emetic or salts of lead. It gives a precipitate with gelatine and the vegetable alkaloids, and turns rapidly brown or black in presence of air and caustic alkali.

Tannic acid is a glucoside, decomposed by acids into a

peculiar sugar and gallic acid, as seen by the following formulæ:—

Gallic acid presents itself under the form of fine, white, silky needles, and is soluble in water, alcohol, and ether. Under the influence of a temperature of 470°F. , it unfolds itself into carbonic acid and a beautiful white crystalline compound called pyrogallic acid, which has of late years been extensively employed in photography. If the temperature be raised to a higher point than the one above mentioned, gallic acid is decomposed into carbonic acid, water, and gallhumic acid. The first decomposition may be represented by the formulæ—

the second as—

Gallic acid has been produced artificially by the action of potash on a di-iodosalicylic acid. When sulphuric acid is made to act on gallic acid, it transforms it into a red acid called rufgallic, which has the formula $\text{C}_7\text{H}_4\text{O}_4$. When in contact with alkalis, in presence of air, gallic acid, like pyrogallic and tannic acids, and various other organic substances, rapidly absorbs oxygen, as was shown by M. Chevreul in 1820. On this fact, Liebig, in 1838, founded an elegant method of determining the amount of oxygen in a mixture of gases. The process, is however, only approximately correct, as I proved in 1863, that under these circumstances oxide of carbon was liberated.

Gallic acid gives a purple-black precipitate, with per-salts of iron, but none with the proto-salts. It gives no precipitate with gelatine, which is a most important fact, as I shall now proceed to show.

Tannin matters, such as oak-bark, are employed for tanning leather, and the conversion of a hide into leather depends on the gradual transformation of the animal matter which it contains into gelatine. This combines with the tannic acid, producing an insoluble compound which fill the pores of the animal tissue, and thus contributes, not only to prevent its putrefaction, but to render it impermeable to water. The value, therefore, of a tannin matter depends on the amount of tannic acid it contains, the gallic acid taking no part in the tanning of the hide.

Tannin substances, such as gall-nuts, sumach, or bark, contain a ferment, which is susceptible of unfolding the glucoside tannic acid into sugar and gallic acid. It is necessary, therefore, that the tanner take great care in the management of the vats, to prevent any fermentation, especially the one called ropiness, for in such a case the vat would become useless. As it is a difficult matter often in summer to prevent this state of things, I may state that I have found that the addition of a few thousandths of carbonic acid is sufficient to prevent these chemical changes, without interfering with those which must take place in the hide.

Tannin matters, as you are aware, are much employed for producing blacks on fabrics, mordanted with per-oxide of iron. I asked myself some years since, whether it was the tannic or the gallic acid which produced the black, or if both participated in its production, and the results of my experiments clearly proved that tannic acid alone took part in its formation. This may be seen if two pieces of calico mordanted with iron are dipped, the one in a solution of tannic acid, and the other in a solution of gallic acid. Both pieces at first become dyed, but after a few days, the one dipped in tannic acid remains black, while in the one dyed with gallic acid the colour has disappeared, the gallic acid having reduced the per-

oxide of iron to the state of protoxide, which, as I have already remarked, does not produce a black with these acids.

As gallic acid is of no value to the dyer as a colour-giving principle, he must take care that his tannin matters, such as sumach, are carefully stored and kept dry, so as to avoid any gallic fermentation taking place, which would decrease the amount of tannin they contain. He should also avoid holding a large stock, as the fermentation above mentioned slowly proceeds in the tannin matters, as is proved by the fact of sumach, for example, decreasing considerably in value, after it has been some time prepared.

(To be continued.)

ON MEASURING TEMPERATURES BY ELECTRICITY.*

By C. WILLIAM SIEMENS, D.C.L., F.R.S., M.R.I.

THE truth revealed to us by one of the younger branches of physical science, which has been cultivated and expounded nowhere more effectually than within these walls, has divested heat and electricity of their mysterious character, and has taught us to regard them simply as "modes of motion."

Light also has been shown to be identical in its nature with heat, and the only remaining physical agency, "chemical affinity," has been recognised as a force differing only in "quality of action" from the others. According to these views, force, in whichever type of action it presents itself, is as *indestructible as matter itself*, and is therefore capable of being *stored up* and *measured* with the same certainty of result. We have a

FIG. 1.

unit of force or the foot-lb., and a unit of heat, or the heat necessary to raise the temperature of 1 lb. of water through 1°F. , and it has been already proved that 772 units of force are the equivalent value of one unit of heat. Again, the chemical force residing in 1 lb. of pure coal is equal to about 14,000 heat units, or $14,000 \times 772 = 10,808,000 \text{ ft.-lbs.} = 4825 \text{ tons lifted 1 foot high.}$

Questions regarding the quantitative effects of heat present themselves, however, much less frequently for our consideration than questions regarding its *intensity*, upon which depends the nature of the phenomena surrounding us at every step, both in science and in ordinary life. The instrument at our command for

* Read before the Royal Institution of Great Britain.

determining moderate intensities or temperatures, the mercury thermometer, leaves little to be desired for ordinary use; but when we ascend in the scale of intensity, we soon approach a point when mercury boils, and from that point upward we are left without a reliable guide. The result is, that we find in scientific books on chemical processes, statements to the effect that such or such reaction takes place at a *dull red* heat, such another at a *bright red*, a *cherry-red*, a *blood-red*, or a *white heat*—expressions which remind one rather of the days of alchemy than of chemical science of the present day.

There are pyrometers, it is true, but these are either of a complex nature, or little reliance can be placed on them.

It is my purpose this evening to place before you an instrument by which I hope to fill up to some extent the existing gap. It is the result of occasional experimental research, spread over several years, and it aims at the accomplishment of a double purpose, that of measuring high temperatures, and of measuring with accuracy the temperatures of *inaccessible* or *distant* places.

But before entering upon the details of my subject, I propose to place before you an instrument which fulfils, in principle, all the conditions essentially necessary in thermometry, and is at the same time the very first instrument that was ever proposed for measuring temperatures. I speak of the *air thermometer* by Galileo. It can be shown on theoretical grounds, that the expansion of a permanent gas at constant pressure is the most perfect index of temperature. It is, in fact, the degree of energy of the atomical motion in an elastic fluid which determines its volume, and which constitutes at the same time its temperature.

The air thermometer consists simply of a bulb of glass with a long tubular stem, open to the atmosphere at its extremity. If I heat the bulb (by dipping it for instance into boiling water) and put it into a holder, with the hollow stem reaching downward into a cup of mercury, the air within the bulb will no longer communicate directly with the atmosphere, because the mercury is interposed. If now I cool the air within the bulb, by the external application of iced water, its heat motion will diminish, and its volume would be reduced proportionally, if the external atmosphere could enter freely to fill up the vacancy thus created. But inasmuch as the external air cannot enter, a reduction of pressure will take place, which, according to the law of elasticity by Boyle, must be proportionate to the reduction of volume at constant pressure. The difference of pressure thus created between the bulb and the external atmosphere will be balanced by the column of mercury rising up into the tube, and the elevation to which the mercury attains is a true index of the temperature to which the air in the bulb had been previously heated. This is true with regard to all temperatures, from the lowest to the highest, and the instrument may be termed a universal thermometer. If the bulb could be cooled down to 273° C. below the zero point, it would follow by the law of Charles that the elastic pressure of air would be reduced to nothing, that is to say, the motion of the particles of air, which we call heat, would have ceased, and we should have reached the point of absolute zero, a point which has been theoretically established also by other means.

Practically, such an instrument would be most inconvenient: its indications would have to be corrected by calculation for barometrical variations; the capacity of the descending tube, which contains air not subjected to variation of temperature, would have to be taken into account, and no reliable observations could be arrived at, without taking special precautions, such as are only within reach of the experimental physicist.

[The other known methods of measuring ordinary and furnace temperatures were here passed in review, and the limits of their application pointed out. They were classified into:—

Thermometers, by expansion of liquids.

Thermometers, by the expansion of solids.

Pyrometers, by chemical decomposition of solids, comprising Wedgwood's and Deville's pyrometers.

Pyrometers, by observing the melting-point of metals.

Pyrometers, by thermo-electricity.

Pyrometers, by exposing a copper or platinum ball of known heat capacity to the heat to be ascertained, and of quenching it in a measured quantity of water.]

The instrument which forms the subject matter of my discourse presents many points of analogy with the air thermometer, if we substitute "*electrical resistance in conductors*" for "*expansion of gases*!" Both these effects are functions of temperature, increasing with the temperature according to progressive laws, which in the case of the gases we call the *law of Charles*, and in the case

FIG. 2.

Full size.

of conductors, the law of "*increase of electrical resistance with temperature.*" The latter law, which is of recent origin, had already been partially developed by Arndsen, Swanberg, Lenz, and Werner Siemens, when my attention was directed, in 1860, towards an application of the same to the measurement of temperatures at places inaccessible to the ordinary thermometer. By means of the contrivance which I shall describe presently, I was enabled to tell, in the testing cabin of a cable-ship, the increasing temperature of the interior of the mass cable in the hold, and to prove the necessity of transhipment of the same into a vessel fitted with water-tight tanks, which have been resorted to ever since, to avoid the danger of softening the gutta-percha covering.

I have arranged an apparatus for proving to you in the first instance that the conductivity of a wire of platinum or other metal is greatly influenced by its temperature; for this purpose I direct the current of a galvanic battery

at will through two branches of equal resistance, each branch comprising a free spiral wire of platinum and one of the coils of a differential galvanometer. By throwing the powerful light of an electric lamp upon the face of the differential galvanometer, and by throwing the image by means of a mirror and lens upon the screen, the audience will see any movement of the needle to the right or the left that may take place when I complete the battery connection. The resistance of both branch circuits being the same, no deflection of the needle is observable on depressing the key, but when I pass the flame of a spirit-lamp under the one platinum coil the needle is thrown immediately over to the right, because the electrical resistance of the heated wire is increased, and consequently a larger proportion of the current is passing through the cooler circuit, exercising a preponderating influence upon the galvanic needle. When I withdraw the spirit flame from the wire, the needle rapidly returns to its zero position, but in passing it under the other spiral wire the needle immediately deflects in the opposite direction.

If, instead of using the open spirals, I were to wind thin insulated wire of any pure metal upon two small cylindrical pieces of wood, and were to enclose the tiny spirals in small silver casings, as shown (in view and in section) by Fig. 2, taking care that the extremities of the spiral wires were soldered to thicker insulated wires, leading respectively to the battery and differential galvanometer before mentioned, it follows that no deflection of the needle ensues when both the protected and equal spirals are dropped into a jar containing iced water. But if I take one of the spirals from the water, and place it, for instance, by his kind permission, into the hand of our President without disconnecting the same from its leading wires, the balance of resistance will no longer take place,

FIG. 3.

and a deflection of the needle to the right actually takes place. I will now endeavour, however, to re-establish the equilibrium by adding warm water to the iced water surrounding the comparison coil near me until no deflection of the needle is observable. This result being obtained, it follows that the temperature of the water surrounding the one coil must be identical with the temperature of our President's hand, and the delicate mercury thermometer which I have placed in my solution must give me the temperature of the distant place which I intended to measure. The temperature here observed is 89.5° F., which is at this moment that of Sir Henry Holland's hands. This result is independent of the ratio in which the electrical resistance increases with temperature in the similar coils, and considering that the silver casings containing the coils are not larger than small pencil-cases, this method might be advantageously employed in physiological research. The one coil would only have to be placed within the cavity to be measured to enable the observer to read the temperature from time to time, without disturbing the patient, with the accuracy of which the mercury or spirit of wine thermometer employed is capable. But the same method is applicable for measuring the temperatures of distant or inaccessible places, such as the interior of stores or cargoes of materials liable to spontaneous combustion; of points elevated above the surface of the ground; or of great depths below for meteorological purposes; or for measuring the temperature of the sea continuously in attaching such a coil to the mariner's sounding-lead. An error would in such cases arise, however, through the uncertainty of the resistance of long leading wires, if a complete remedy of error from such a source had not suggested itself. This

consists in uniting three separate insulated leading wires into a cable by which the distant coil is connected with the measuring instrument. One galvanic circuit passes from the battery through one of the leading wires, through the distant spiral, and back again through the second leading wire to the differential galvanometer and the battery, and the second passes from the same battery through the near coil, and through the third leading wire up to the distant coil without traversing the same, and back again through the second leading wire to the galvanometer and battery. Thus both galvanic circuits comprise the leading wires up to the distant coil, and all variations of resistance by temperature to which the leading wires may be subjected affect both sides of the balance equally. In constructing coils for measuring deep-sea temperatures, a large quantity of insulated copper or iron wire is wound upon a metallic tube open at both ends to admit the sea-water freely, in order to impart its temperature to the innermost layers of the insulated wire. The coil of wire is protected externally by drawing a tube of vulcanised india-rubber over it, which in its turn is bound round by a close spiral layer of copper wire, whereby the sea-water is effectually excluded from the sensitive coil. By these arrangements, the temperature of distant or otherwise inaccessible places can be accurately ascertained; but the method is limited to the range of temperature which can be obtained and measured in the comparison bath. In order to realise a pyrometer by electrical resistance, it is necessary to rely upon the absolute measurement of the electrical resistance of a coil of wire which must be made to resist intense heats without deteriorating through fusion or oxidation. Platinum is the only suitable metal for such an application, but even platinum wire deteriorates if exposed to the direct action

of the flame of a furnace, and requires an external protection. The platinum wire used has, moreover, to be insulated and supported by a material which is not fused or rendered conductive at intense heats, and the disturbing influence of leading-wires had in this case also to be neutralised. These

various conditions are very fully realised by the arrangement represented on the diagram, Fig. 3.

Thin platinum wire is coiled upon a cylinder of hard-baked porcelain, upon the surface of which a double-threaded helical groove is formed for its reception, so as to prevent contact between the coils of wire. The porcelain cylinder is pierced twice longitudinally for the passage of two thick platinum leading wires, which are connected to the thin spiral wire at the end. In the upper portion of the porcelain cylinder the two spiral wires are formed into a longitudinal loop, and are connected crossways by means of a platinum binding-screw, which admits of being moved up or down for the purpose of adjustment of the electrical resistance at the zero of Centigrade scale. The porcelain cylinder is provided with projecting rims, which separate the spiral wire from the surrounding protecting tube of platinum, which is joined to a longer tube of wrought-iron, serving the purpose of a handle for moving the instrument. If the temperatures to be measured do not exceed a moderate white heat, or, say, 1300° C. = 2372° F., it suffices to make the lower protecting tube also of wrought-iron, to save expense. This lower portion only, up to the conical enlargement or boss of iron, is exposed to the heat to be measured. Three leading wires of insulated copper united into a light cable connect the pyrometer with the measuring instrument, which may be at a distance of some hundred yards from the same. They are connected by means of binding-screws at the end of the tube to three thick platinum wires passing down the tube to the spiral of thin platinum wire. Here two of the leading wires are united, whereas the third traverses the spiral, and joins itself likewise to one of the two former, which forms the return wire for two electrical

circuits, the one comprising the spiral of thin wire, and the other returning immediately in front of the same, but traversing in its stead a comparison coil of constant resistance. The measuring instrument may consist of a differential galvanometer as before, if to the constant resistance a variable resistance is added. If the pyrometer coil were to be put into a vessel containing snow and water, the balance of resistance between the two battery circuits would be obtained without adding variable resistance to the coil of constant resistance, and the needle of the differential galvanometer would remain at zero when the current is established. But on exposing the pyrometer to an elevated temperature, the resistance of its platinum coil would be increased, and resistance to the same amount would have to be added to the constant resistance of the measuring instrument, in order to re-establish the electrical balance. This additional resistance would be the measure of the increase of temperature, if only the ratio in which platinum wire increases in electrical resistance with temperature is once for all established. This is a question which I shall revert to after having completed the description of the pyrometric instrument.

(To be continued).

CORRESPONDENCE.

ESTIMATION OF COPPER.

To the Editor of the Chemical News.

SIR,—I have read Mr. Hugo Tamm's articles on the "Estimation of Copper," &c., and Mr. Alfred Allen's sensible remarks thereon, and I beg leave to say that it is incredible to me that any one should bring forward at this late day a method of determining copper which requires a precipitation, when the deposition of copper on platinum by the galvanic current affords so elegant and exact a process.

I am required occasionally to determine copper in pyrites, and never dream of using any other method than that of which the following is an outline. Treat the pyrites with nitric acid to complete oxidation of the sulphur, evaporate to dryness, and ignite gently; then treat with a small amount of boiling water, and sufficient ammonia to precipitate and re-dissolve the copper. Filter the blue solution from the silica, iron oxide, &c., wash the filter, concentrate the washings if need be, make the filtrate sharply acid with sulphuric acid, and plate out the copper on the inside of a platinum dish which is made the cathode of a battery of the two small Grove's cells, the anode being a stout platinum wire hung in the solution. For a tolerably close result—generally sufficient in technical work—the solution in ammonia may be omitted, and the copper directly plated over from the solution filtered from the silica, &c. This method is steadily gaining favour here, and I am surprised that it has not already supplanted all other methods.

I should be glad to hear any objection raised against it by some one who has given it a fair trial. For the exact determination of very minute quantities of copper no method can approach it.—I am, &c.,

J. M. MERRICK.

Laboratory, 59, Broad Street, Boston, U.S.A.,
August 31, 1872.

PAPER FOR TELEGRAPHY.

To the Editor of the Chemical News.

SIR,—I read in the CHEMICAL NEWS, vol. xxvi., p. 60, that one of your correspondents ("T. R.") is desirous to obtain a good conductible paper, without being obliged to moisten the paper continually. I believe that I can be of some service to him, as I met with the same difficulty a couple of years ago, working in New York with the Caselli and the Lenoir autographic telegraph.

As you know, the telegram to be sent is written with an isolating ink on paper silvered by a very thin film of silver. This isolating ink was invariably composed of a gum resin solution, which had the effect of adhering to the points of the metallic comb, and thus interfering with the conductivity. I suppressed this gum ink, which I replaced by a strong solution of chromic acid, having the action of forming a chromate of silver, destroying the conductivity (being a bad conductor), and drying at once. I recommend your correspondent to employ it.

In order to obtain my receiving-paper prepared with ferrocyanide of potassium in a constant moist state, after a great many experiments I used glycerine, and obtained the very best results. I first prepare my solution of ferrocyanide of potassium, and then add the glycerine, about half of each solution. This preparation has been adopted by the Superintendent of the Western Union Telegraph, Mr. Ludovic, of New York, for the autographic telegraphs of Little. As for the points of contact, I prefer red copper to iron; the iron, being so soluble, spreads too much, and sometimes, when very fine lines are required, blots the work; copper has not the same effect.—I am, &c.,

C. WIDEMANN.

15, Rue Trévis, Paris, Sept. 22, 1872.

POWERFUL GALVANIC BATTERY.

To the Editor of the Chemical News.

SIR,—A friend has just pointed out to me that in a number of your Journal about a month since, which I did not happen to see, questions were asked in your "Notes and Queries" with respect to my batteries. As it would take up too much of your space to answer the queries fully, and it is always more satisfactory to show a thing than give a description of it, I will only say that I shall be glad, by appointment, to show anyone the construction of my batteries, and to show them a copy of the figures resulting from the experiments which I went through to ascertain the points on which I was to give explanations.—I am, &c.,

H. HIGHTON.

2, The Cedars, Putney, Sept. 19, 1872.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 16, 1872.

This number contains no original papers relating to chemistry; the contents are chiefly devoted to astronomy.

Annalen der Chemie und Pharmacie, No. 10, 1872.

This number contains the following original memoirs and papers:—
Mononitro-Resorcin.—P. Weselsky.—While trinitro-resorcin is easily prepared by treating resorcin with nitro-sulphuric acid, the mono-, nitro-, and dinitro-resorcin are obtained with difficulty. By direct nitration, the author obtained mononitro-resorcin as a by-product of the preparation of diazo-resorcin. He describes at great length the method of purifying the mononitro-resorcin, which, in pure state, exhibits a pure lemon-yellow colour, is not bitter to the taste, is not explosive, and is not sublimable without decomposition; its fusing-point is 115°. The following bodies are also described:—Monobasic baryta salt—

hydrochlorate of mono-amido-resorcin—

bromnitro-resorcin fuses at 147°; formula—

Constitution of the Phosphorus Compounds.—A. Michaelis.—The first instalment of an exhaustive monograph on this subject. Notwithstanding the high scientific value of the contents, elucidated by a series of algebraical and chemical formulae, this paper is not suited for abstraction; it is divided into the following sections:—General introduction, treating on the phosphor compounds in general; sulphobromides of phosphorus; pyrophosphorus sulphobromide, $P_2S_2Br_4$; triethoxyl-pyrophosphor sulphobromide, $P_2S_2(OC_2H_5)_4Br$; pyrosulpho-phosphoric acid ethyl ether, $P_2S_2(OC_2H_5)_4$; diethoxyl-diethylsulphyl-pyrosulpho-phosphoric acid ether—

orthophosphor sulphobromide, $PSBr_3$.

Formation of Sulphur Metals.—E. Priwoznik.—This memoir contains the record of some experiments made with different kinds of metals, by immersing them into a deep yellow-coloured sulphhydrate of ammonium, to which some sulphur had purposely been added; cadmium, lead, bismuth, antimony, zinc, and aluminium, are scarcely acted upon by being kept for several months in a solution of alkaline supersulphurets, care being taken that these metals are quite clean and polished previous to immersion; but, as regards copper, tin, silver, nickel, and iron, the case is different. Perfectly pure copper assumes a dark colour on being immersed in the sulphur compound of ammonium, and in a short time it is converted into monosulphuret of copper of a blue colour; but when the metal is kept immersed in the aforesaid solution for a considerable time, the blue colour changes to black, and, on analysis, the compound is found to be semi- or sub-sulphuret of copper, Cu_2S . Chemically pure silver becomes, as is generally known, very readily converted into sulphuret by the action of either sulphuretted hydrogen or alkaline sulphurets. When silver is exposed for a longer time to the action of the ammonium solution, the metal is converted into sulphuret of silver, Ag_2S . Tin also forms sulphur compounds under the above conditions, but, owing to the solubility of the sulphur compounds of tin in solutions of alkaline sulphurets, the tin is dissolved; 6.84 per cent of pure Banca tin had been dissolved in eight days. Nickel behaves like tin and iron (bright iron wire 1 m.m. thick), and is slowly and gradually coated with a thin layer of sulphuret.

Sulpho Acids of Mesitylen.—H. Rose.—This exhaustive essay is divided into the following sections:—Mesitylen-sulpho acid—

baryta, lead, and magnesia salts of this acid; brom-mesitylen-sulpho acid from mesitylen-sulpho acid; baryta, lead, potassa, soda, lime, and copper salts of this acid (the formula of the copper salt is—

brom-mesitylen-sulpho acid from monobrom-mesitylen and salts of this compound; nitro-mesitylen-sulpho acid from mesitylen-sulpho acid; formula of nitromesitylen-sulpho acid—

and salts of this acid; amidomesitylen-sulpho acid—

Studies on the Combinations of the Camphor Group.—J. Kachler.—The third instalment of a lengthy monograph on this subject; this part, elucidated by a series of complex formulae, and extensive tables exhibiting the physical properties, sp. gr., boiling-point, vapour density, and behaviour with reagents, of several of the compounds of the camphor group, is divided into the following sections:—Borneol (camphol), $C_{10}H_{18}O$; phoron and camphren, $C_8H_{14}O$; camphrenic acid, $C_8H_{14}O_4$.

Monochlorocrotonic Acid Obtained from Croton Chloral.—C. Sarnow.—The preparation of monochlorocrotonic acid from trichlorocrotonic acid, by the aid of water and metallic zinc-powder, is described, along with the rather tedious process of purification, at great length. In pure state, monochlorocrotonic acid is a solid crystalline substance, difficultly soluble in cold, more so in boiling-hot water, and very readily so in alcohol and ether; fusing-point, 96°; boiling-point, 212°, yet very volatile and sublimable at 100°. Although this acid agrees in many of its properties with monochlorotetracrylic acid (first obtained by Geuther), it (monochlorocrotonic acid) is not identical therewith. A large number of salts and ethers of this acid are described at length, and, further, the following bodies:—Monochlorocrotonid, $(C_4H_5ClO.Cl)$; monochlorocrotonamid—

monochlorocrotonitrile, $(C_4H_5Cl.N)$; monochlorobibrombutyric acid, $(C_4H_5ClBr_2O_2)$; salts of this acid.

Some of the Derivatives of Dioxycbenzoic Acid.—L. Barth and C. Senhofer.—Notwithstanding the scientific merits of this essay, its contents are not well suited for any useful abstraction.

Toluol-Disulpho Acid and some of its Derivatives.—C. Senhofer.—Toluol-disulpho acid is prepared by the action of a mixture of phosphoric anhydride and sulphuric acid upon toluol, the substances being placed in a tube, which, after having been sealed, is heated to 330° for some five hours. The purification of the raw material is a rather tedious affair; the author prepared some of the free acid, in pure state, from the baryta salt of the air-dry toluol-disulpho acid—

The free acid is a solid substance, readily decomposable at 100°. In addition to several salts of this acid, the following derivatives thereof are described:—Isorcin; isoxylidinic acid.

Action of Fusing Caustic Potassa upon Benzoic Acid.—L. Barth.—This lengthy memoir treats on the products obtained by the fusion together of benzoic acid and solid caustic potassa, the operation being conducted in a silver vessel. Para-oxybenzoic acid is the main product; further, an acid, $C_{10}H_8O_4$; and an amorphous, yellow-coloured, resinous body, insoluble in water.

Sulpho-Para-Oxybenzoic Acid.—R. Kölle.—The preparation of this acid is described at length. The pure substance is a solid deliquescent body, soluble in alcohol, but insoluble in ether; fusing-point, below 100°. Among the salts, the potassa salt is described at length; it is crystalline; its formula is $C_7H_5K_2SO_4 + 2H_2O$.

Researches on Kynurenic Acids and Kynurin, the Product of Decomposition of these Acids.—Drs. O. Schmiedelberg and O. Schultzen.—The name of this acid is derived from *kynos*, "a dog," the acid being met with in dogs' urine, and obtained from it by a rather difficult process of operation. Pure kynurenic acid is a solid, crystalline, needle-shaped body, insoluble in water, and also in water acidulated with either hydrochloric or nitric acids, but somewhat soluble in these acids when concentrated, and also pretty soluble in boiling alcohol; the acid fuses at 266°, but is then somewhat decomposed, much gas being evolved; with baryta, kynurenic acid forms a rather difficultly soluble salt. The formula of the free acid is—

that of the baryta salt is $C_{10}H_{11}N_3O_4Ba + 3H_2O$. Kynurin is the substance which is obtained by fusing the kynurenic acid at 265° on an oil-bath; much carbonic acid is given off, and, after purifying, a solid, crystalline, neutral body is obtained, slightly soluble in alcohol, and fusing at 201°; formula, $C_{10}H_{11}N_3O_3$.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
June 16, 1872.

Studies on Dynamometers.—C. Mène.—The continuation of an essay on this subject, illustrated with woodcuts.

Preparation of Nitrite of Amylen for Pharmaceutical Use.—C. Mène.—From the crude alcohol of commerce, this substance may be prepared in the following manner:—The crude alcohol, which is readily obtained in France, is first washed with a concentrated aqueous solution of common salt, and then with a large quantity of water, after which the remainder is submitted to distillation in a retort, to which a thermometer is fitted; that which distils over below 125° is set aside as unsuitable, but the distillate from 125° to 140° is kept and rectified at 132°. The amylic alcohol thus obtained is poured into another retort, fitted with a safety-tube; some clean copper wire having been put into the retort, a mixture, of about one-tenth each of the bulk of the alcohol, of sulphuric and nitric acids is then added. The temperature is gently raised to 65°; nitric acid is again added to the liquid in the retort, and the operation of distillation re-commenced until red vapours appear; the product is then washed with caustic soda solution, and re-distilled over carbonate of potassa. The portion which distils over between 95° and 100° is nitrite of amylen, sufficiently pure for pharmaceutical use. Amylic alcohol may be obtained in this country from manufacturing chemists, thus saving the trouble of separating it from crude alcohol.

La Revue Scientifique de la France et de l'Etranger,
September 7, 1872.

This number contains no original papers relating to chemistry or collateral subjects.

September 21, 1872.

The contents of this number are devoted to the record of the proceedings of the Bordeaux meeting of the French Association for the Advancement of Sciences. The President of the Chemical Section is Professor Balard; Honorary Presidents, Drs. Stas and Von Baumhauer; Vice-President, Dr. Wurtz; Secretary, M. Lecoq de Boisbaudran. From the condensed report of the proceedings we glean the following:—Prof. Berthelot gave a concise, yet extensive, *resume* of his researches on the condition of bodies when in solution, pointing out the important bearing of the results obtained by him as regards its application to the study of wines, mineral waters, blood, milk, urine, &c., and molecular mechanics. M. Jungfleisch, after briefly alluding to Pasteur's researches on the synthesis of racemic acid, and also to those of Dessaigne, Perkins, and Duppa, stated that all substances derived from tartaric acid by elimination of water regenerate, by absorption of that fluid, tartaric acid, which turns the plane of polarisation to the right, but, as soon as the tartaric acid is submitted, in the presence of water, to a high temperature, this does not further obtain; at 175° a considerable portion of racemic acid is formed, while the mother-liquor from that acid contains a quantity of inactive (optically) tartaric acid; these facts are of general application. Anhydrous camphoric acid regenerates the acid from which it was obtained when, however, camphoric acid is heated in the presence of water, other products, differing from anhydrous camphoric acid, are formed. Dr. Schützenberger gave a brief account of his researches on platinum compounds; by causing oxide of carbon to react upon bichloride of platinum, three different products are obtained, according to the conditions under which the operation is conducted, viz., $COPtCl_2$, $C_2O_2PtCl_2$, and a compound of these two. Perchloride of phosphorus attacks platinum at 250°, and gives an analogous compound, $PhCl_2PtCl_2$, which crystallises, and yields in its turn, with $PhCl_3$, another canary-coloured product, $(PhCl_2)_2PtCl_2$; in contact with water, the product $PhCl_2PtCl_2$ is converted into a hydrate—

a veritable acid, which yields, with lead, a compound—

which is a detonating salt. With alcohol, $\text{PhCl}_2\text{PtCl}_2$ yields a crystalline compound, fusing at 83° , and yielding chloride of ethyl when heated to 180° , leaving a compound, $\text{Ph}(\text{C}_2\text{H}_5\text{O})_2\text{PtCl}_2$; by further heating, this compound is converted into chlorhydric acid, ethylene, polyphosphoric acid, and platinum. The compounds of ammonia and $\text{Ph}(\text{C}_2\text{H}_5\text{O})_2\text{PtCl}_2$, and derivatives therefrom, are next alluded to, and, lastly, the series of the compound $(\text{PhCl}_2)_2\text{PtCl}_2$. M. Henninger gave a brief account of his (and Vogt's) researches on the synthesis of orcin. Filhol discussed the condition in which sulphur is met with in the mineral waters of the Pyrenees. In the Section for Civil and Military Engineering, M. E. Lemoine read a lengthy paper on the repartition of the pressure in a network of gas-mains and on the best means to regulate that pressure. Among the papers read in the Mathematical Section, we notice a memoir by M. Saint-Loup, on the elastic force of vapours in relation to temperature. M. Hureau de Villeneuve explained the construction and management of a new kind of steam-boiler, which is heated by petroleum, and appears to possess great advantages, especially as regards prevention of loss of heat. In the Zoological Section, important and practically available communications are made on ostraciculture, especially in reference to the labours of MM. Michelet and Austchysky at the Bay of Arcachon, where oysters are now cultivated on a large scale. To this number is added the list of the names of all the members of the Association.

Polytechnisches Journal von Dr. E. M. Dingler, second number for August, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Application of the Water Air-Pump to Evaporation, Distillation, Filtration, &c., in Vacuum.—F. A. Wolff and Sons.—This paper, illustrated by engravings, contains the record of a series of technical experiments made with a contrivance somewhat like Bunsen's air-pump (described by Winkler in *Dingler's Polytech. Journ.*, vol. xciv., p. 34, 1870). It appears that many of the industrial operations may be more rapidly and advantageously conducted by the aid of a vacuum.

Basic Carbonate of Lime in Hydraulic Cements.—A. R. Schulatschenko.—The contents of this exhaustive monograph, elucidated by a large number of analyses of limestones and cements, may be resumed as follows:—The formation of basic carbonate of lime as a consequence of the incomplete burning of the limestone is doubtful; the incomplete burning of aluminous limestones (*thonhaltige kalksteine*) rarely yields good results. Considering the excellent quality of the Roché cement, the author thinks that the Wolchow (Russia) aluminous limestone will yield a cement of better quality.

Studies for Establishing a Scientifically-Arranged Tanning Method.—A. Reimer.—The continuation of an exhaustive essay, this portion being divided into the following sections:—Skin (hide) with alum and common salt; mixture of equal parts of the two last-named salts; sulphate of alumina only; acetate of alumina.

Test for the Adulteration of Beer with Caramel.—Dr. R. Schuster.—The author states that when beer is mixed with a solution of tannic acid, and thoroughly shaken, it is discoloured when malt only has been used, but, when caramel has been added, the colour remains unaltered.

Estimation of Acetic Acid in Wine.—E. Kiesel.—The wine is first neutralised with baryta; next, the alcohol is distilled off; and then phosphoric acid is added, and the liquid re-distilled; the distillate contains the acetic acid.

Bayerisches Industrie und Gewerbe-Blatt, August, 1872.

Aluminium-Plating.—Dr. C. Winkler.—This memoir contains a discussion on the methods and practicability of coating other metals with aluminium. From the author's researches on this subject, it appears that neither galvanoplastically, nor also by the well-known method of plating, the object in view can be obtained.

Methods of Detecting and Quantitatively Estimating Paraffin in Stearine Candles.—M. Hock.—After reviewing the various methods employed for this purpose, the author states that it is best to saponify the stearine (really stearic acid) with moderately strong caustic potassa, to convert the soap thus obtained into a soda-soap, by means of chloride of sodium, and to treat the soda-soap on a filter, first with cold water, and next with some dilute alcohol; the soap is dissolved, and the paraffin set free; the filter is then dried at a temperature of about 35° , after which the paraffin is dissolved in ether, and this solution evaporated, and the residue weighed. This method has been tried by the author with mixtures of known quantities of stearine and paraffin, and found to answer well.

French Putty.—Ruban.—7 pounds of linseed oil are boiled with 4 pounds of brown umber for about two hours; 62 grms. of chips of wax are then added to the oil. After having been removed from the fire, a mixture of 54 pounds of chalk and 11 pounds of dry white-lead is added to the oil. This putty is stated to be very durable, and to adhere strongly to wood which has not been painted.

Very Durable Crucibles for Smelting Steel and other Metals.—Dr. G. Feichtinger.—These crucibles are made with the following mixture:—Ground-up and lixiviated porcelain mass, 10 parts; graphite, 10 parts; asbestos (cut up into threads of some 3 m.m. length), 15 parts; powdered quartz, 3 parts; fire-clay, 22 parts.

Archives Néerlandaises des Sciences Exactes et Naturelles, Vol. vii., No. 2, 1872.

The following original papers and memoirs relating to chemistry and collateral subjects are published in this number:—

Influence which the Temperature Exerts upon the Rotatory Power of Tartaric Acid and Tartrates.—F. W. Krecke.—This lengthy essay, illustrated by woodcuts, is divided into the following sections:—Introduction, containing a concise review of the labours of Biot and others, and of the general laws of rotation of organic bodies; method of observation; influence of temperature upon the specific rotatory power of tartaric acid; influence of the temperature upon the specific rotatory power of the tartrates, viz., of potassa, soda, ammonia, sal-seignette, potassio-tartrate of antimony; conclusions. The paper contains a series of tables exhibiting results of experiments.

Determination of the Temperatures in the Experiments of M. V. Regnault on the Elastic Force of Aqueous Vapour and Steam.—J. Bosscha, jun.—This essay, elucidated by a series of tables exhibiting results of experiments, is written more particularly to show certain errors in Regnault's work.

Meteorite of Knyahinya, in the Comitát of Ungvár (Hungary).—E. H. von Baumhauer.—This exhaustive memoir contains, in the first place, a detailed account of the phenomena attending the fall of this meteorite on June 9th, 1866, as witnessed by several persons whose evidence was taken in writing by the late Chevalier W. von Haidinger. The second portion is devoted to the chemical analysis and method of investigation applied. The composition of this stone is, in 100 parts:—Nickeliferous iron, 50; sulphuret of iron, 22; chrome iron, 0.8; olivine, 39.9; insoluble bisilicate, 52.1.

Meteorite de l'Aigle, Département de l'Orne, France.—E. H. von Baumhauer.—This meteorite fell on April 26th, 1803. A record is given of the analysis of this stone, which was found to contain, in 100 parts:—Nickeliferous iron, 80; sulphuret of iron, 1.8; chrome iron, 0.6; sulphate of lime, traces; olivine, 45.3; bisilicate, 44.3.

Although not strictly relating to chemistry, we quote the titles of the following essays:—

Poisoned Arrows of Africa.—A. W. M. van Hasselt.—The results of physiologico-toxicological experiments made with, and the botanical origin of, the arrow-poison used in Africa.

General Report on the Observations of the Total Eclipse of the Sun of December 12th, 1871, drawn up from the Reports of various observers in the Island of Java by Dr. Oudemans, Chief Engineer of the Geographic Bureau at Batavia.

Artificial Production of some of the Principal Formations of Organic Calcareous Origin.—P. Harting.—This paper, illustrated by woodcuts, records the author's ingenious investigations, by which he has artificially produced calcareous forms exactly like those made by the lower orders of animal life.

Vol. vii., No. 3, 1872.

This number contains, in addition to several original papers and memoirs relating to mathematics and natural history, the following original papers relating to chemistry:—

The Chemical Process (Chimisme) of Respiration Considered as a Phenomenon of Dissociation.—F. C. Donders.—Reserved for translation.

Mannite and Nitro-Mannite Considered in their Action upon Polarised Light.—F. W. Krecke.—This essay is elucidated by a series of tables. The author's conclusions are:—(1) Mannite which is optically-inactive is converted, by the action of nitro-sulphuric acids, into optically-active nitro-mannite; (2) optically-active nitro-mannite is converted again into optically-inactive mannite by sulphuret of ammonium; (3) optically-active dextrose is converted, under the influence of sodium amalgam or of platinised magnesium (*magnesium platine*), into optically-inactive mannite; (4) the optically-inactive mannite thus obtained is converted by nitro-sulphuric acids into optically-active nitro-mannite; (5) slight molecular changes of bodies are sufficient to convert them from optically-active into optically-inactive substances and vice versa.

Slow Combustion.—P. J. van Kerckhoff.—Reserved for translation.

Primary Normal Hexylic Alcohol Contained in the Essence of the Heracleum Giganteum.—A. P. N. Franchimont and Th. Zincke.—An abstract of this extensive memoir was published in another periodical, and quoted in the *CHEMICAL NEWS* (vol. xxv., p. 57).

Pharmaceutische Zeitschrift für Russland, No. 10, 1872.

The only original paper published in this number is the continuation and conclusion of the memoir—

Relation of Modern Chemistry to Metallurgy.—Dr. C. Winkler
No. 11, 1872.

This number contains no original papers relating to chemistry, but we notice the following memoir:—

Description of some Pharmacognostically Important Objects in Use in Central Asia.—R. Palm.—The author gives an account of the following substances:—Schörum-Dorü is a kind of sea-weed obtained from the salt-lakes of Thibet; the chemical investigation of this substance proved it to contain about 1 per cent of iodine, combined with bases. When boiled with water, this sea-weed (of which a lengthy botanico-pharmacognostical description is given) yields a jelly no

dissimilar to that obtainable by the same treatment from Irish moss (*Lichen Carraghen*). The ash contains sodium, magnesium, alumina, calcium, potassium, oxide of iron, chlorine, iodine, sulphuric acid, silica, phosphoric acid, and carbonic acid; according to the author, no plant has yet been found to contain so large a quantity of iodine as this sea-weed. Sirauwant is a kind of tubercle, which contains 47.57 per cent of starch, 2.88 per cent of salts (ash), and also a peculiar principle, which somewhat resembles emetin, but of which, in consequence of insufficient material, no further investigation could be made. Bucharian nutgalls, locally known as Busgusch, contain 43.10 per cent of tannic acid, 3.03 per cent of a green waxy matter, and 16.0 per cent of cellulose.

Chemisches Centralblatt, No. 35, 1872.

This number contains the following original communications:—

Precipitate Produced in Beer by the Addition of a Solution of Carbonate of Potassa.—A. Metz.—It appears that a concentrated solution of the salt alluded to produces in beer a slight, but distinct, crystalline precipitate (10 grms. of the salt to 1 litre of beer), which consists of hydrated phosphoric oxide of potassa and magnesia— $\text{K}_2\text{O} \cdot \text{MgO} \cdot \text{PO}_3 + 12\text{H}_2\text{O}$.

Preparation of Artificial Fuel from Small Coal and Small (Pulverulent) Anthracite.—F. Loiseau.—By the addition of about 5 per cent of clay to the coaly matter, the author forms it, by strong pressure, into the shape of large-sized bricks, which are next placed in a solution of resin in benzol (benzoline), and then dried; by this process, the artificial fuel is rendered impervious to water, and more readily combustible.

NOTES AND QUERIES.

Gum Copal.—(Reply to C. T. Kingzett).—This resin is not soluble in alcohol, which is the ordinary solvent of resins, but, after having been first softened by pure ether, which renders copal gelatinous, the resin is soluble in alcohol; chloroform dissolves copal readily, but the best solvent is the empyreumatic oil obtained by the dry distillation of caoutchouc, and also the empyreumatic oil obtained when copal is heated above its melting-point, which is between 180° and 340° . Strong liquid ammonia renders copal gelatinous, and, when heated with a concentrated aqueous solution of caustic potassa, it is dissolved. It should be remembered that, under the name of copal, resins of different origin are imported from different countries, and the properties of these differ greatly. By exposure to air, after having been first pulverised, copal absorbs oxygen, and becomes more readily soluble in the solvents mentioned, as well as in oils of turpentine and rosmary.

THE CHEMICAL NEWS.

VOL. XXVI. No. 671.

ON THE OCCURRENCE IN RECENT PINE TIMBER OF FICHELITE, A HYDROCARBON HITHERTO ONLY KNOWN IN A FOSSIL STATE.

By J. W. MALLET, Ph.D., M.D.,
Professor of Pure and Applied Chemistry, University of Virginia.

SOME nearly colourless crystalline crusts found in clefts between the annual rings of growth of a log of long-leaved pine (*Pinus Australis*) in Alabama were found to dissolve in boiling alcohol (more easily in ether), and, on cooling, to crystallise in monoclinic forms with greater distinctness. A specimen was exhibited of this material purified by two or three re-crystallisations; it had been found to agree perfectly in physical and chemical properties with the fichtelite of Bromeis and Clark, and on analysis yielded—

Carbon	87.82
Hydrogen	11.91
	99.73

agreeing with the formula $\pi(C_5H_8)$. The fusing-point was found = $45^\circ C$.

ADJUSTMENT OF VOLUMETRIC TEST- SOLUTIONS.

By F. MAXWELL LYTE, F.C.S.

I BEG to suggest a mode of adjusting the strength of volumetric test-solutions, which offers at least the advantage of dispensing with tedious measurements, and offers a means of a more rapid adjustment where large bulks of liquid are to be dealt with. I cannot do better than simply illustrate my plan, without further explanation, by a practical example.

Let us suppose a deci-normal test-solution of oxalic acid to have been made, and, taking this as a basis, that it is desired to manufacture a solution of soda exactly to correspond with the deci-normal acid. The usual method employed is to make a soda solution more concentrated than requisite, to try how much of this liquid corresponds to a measured volume of the deci-normal acid, and to calculate thence the percentage volumes of soda solution and water which have to be mixed to bring the alkaline solution to deci-normal strength. The adjustment is then obliged to be made by actual, and for large quantities tedious, measurements.

My mode of proceeding is as follows:—Suppose a large jar of soda solution is to be made. I make, first of all, say, half the jar full of solution, which I guess will be nearly double the required strength, over or under the mark, it matters but little which, and I titrate to find out how much of the solution is equal to a given volume of deci-normal acid. I now add a measured quantity, say 200, 500, or 1000 c.c. of water, as the case may be, and I titrate again. This time I shall have brought my alkaline solution somewhat nearer to the deci-normal standard, and, without knowing the bulk of the original alkaline solution, I am able to calculate the percentage effect of my addition of water, and from this, by a simple proportion, I can easily calculate how much water I ought

to have added in order to render the alkaline solution strictly deci-normal.

A jar of about 45 to 50 litres capacity contained soda solution to be adjusted; 88 c.c. of this solution were found to correspond to 100 c.c. of deci-normal acid. 500 c.c. of water were added, and, on titration, it was found that 93 c.c. now corresponded to 100 c.c. of acid. The liquid, then, originally required to be lowered in strength 12 per cent, and the addition of the 500 c.c. of water lowered it 5 per cent; if, then, instead of 500 c.c., we had added 1200 c.c., we should have reduced the solution to deci-normal strength; therefore, to effect this, all we have to do now is to add 700 c.c. more of water, and the liquid is adjusted thus without further measurement or manipulation. Of course, if the alkaline solution had been too weak originally, instead of being too strong, the water added might have been substituted by a strong solution of soda, and the adjustment proceeded with on the same basis.

Paris, Sept. 19, 1872.

ON THE PRESENCE OF GOLD IN SEA-WATER.

By E. SONSTADT.

I HAVE used three entirely different methods for the detection of gold in sea-water, but all the methods were applied to the water itself, not to the residue left on evaporation. The experiments have been made upon specimens collected at different times from different parts of Ramsey Bay, Isle of Man, and the results obtained from the different specimens have been in entire accordance. The proportion of gold contained in sea-water (certainly less than one grain in the ton) is much too small to admit of separation, or even detection, by the usual tests applied in the usual manner. Besides the difficulty of detection arising from the small proportion of gold present, there is another difficulty of a graver kind, due to a continuous re-solution of the gold after it has been separated in the metallic state. This re-solution is owing to the separation of iodine under the influence of reducing agents upon the iodate of calcium, which, in a paper published in the CHEMICAL NEWS, I have shown to exist in sea-water. Even if the reducing agent is added in very large excess, oxidation takes place so rapidly under the continuous re-forming power of iodate of calcium, that, sooner or later, according to the excess of reducing agent used, the stage arrives at which iodine is set free, and the suspended gold is re-dissolved.

I. The first method I shall describe of detecting gold in sea-water may be practised upon so small a quantity of water as 150 or 200 c.c. Two or three decigrammes of pure ferrous sulphate are dissolved in the water, which is acidulated by two or three drops of hydrochloric acid. The solution is heated in a *chemically clean* and well-glazed porcelain dish, over a small flame, so managed that the flame may touch the under part of the dish without causing ebullition. Under these circumstances a lustrous film of ferric oxide forms in the dish, commencing from the portion directly heated by the flame. The heat is continued, without boiling, until the sea-water is evaporated to about half, or so long as the film increases in extent and in lustre. The liquid is then poured off, the strongly adherent film is rinsed with a little water, and then about 50 c.c. of strong chlorine water is allowed to stand in the dish for an hour or two, after which it is slowly evaporated down (over the film) to a few drops, a drop of dilute hydrochloric acid being added towards the end of the evaporation. The liquid, which should be nearly colourless, is then poured into a test-glass containing a few drops of solution of stannous chloride, when, after a few minutes, the liquid takes a bluish or purplish tint, which may be exactly matched by a drop or

* Read before the British Association, Brighton Meeting, Section B.

two of a suitably diluted solution of gold added to a corresponding portion of tin-salt in another glass. The reaction may, of course, be made more striking by taking for the experiment a larger quantity of sea-water, although the reaction obtainable from the quantity indicated is quite definite. I have repeated this experiment many times, upon different specimens of sea-water, and always with the same result when a film was obtained on evaporation. But the formation of this film depends upon the iron being in a particular degree of oxidation, and I have sometimes failed to obtain it. The best way is, after adding the ferrous sulphate and hydrochloric acid to the sea-water, to leave it exposed to the air for a few hours, or over night, before heating the liquid to obtain the film. Corresponding experiments were made, in the same vessels and with the same reagents, upon simple water, and upon water containing chloride of sodium and alkali sulphates in solution, but the films obtained, when treated as described, never gave the slightest colouration with solution of stannous chloride. The chlorine solution off the sea-water films may be dried up in a porcelain crucible with precipitated lead, and gold beads obtained by cupellation, after fusing the lead into a button with borax; but for this experiment at least half a litre of sea-water should be taken, and even then the bead obtained is not ponderable.

II. From half a litre to a litre of sea-water should be taken for the experiment now to be described. As much solution of pure chloride of barium is added to the water as will give about a grain of precipitate. A day or two should be allowed for the precipitate to settle. The precipitate is collected, dried, mixed with borax and lead, and the button of lead obtained before the blowpipe on charcoal is cupelled. The bead obtained is yellowish white, of the same colour as an alloy of 60 parts gold to 40 of silver, or thereabouts. For confirmation of the presence of gold the bead may be dissolved, in a very small test-tube, in a few drops of aqua regia, which is then evaporated, at a gentle heat, nearly to dryness. A few drops of pure hydrochloric acid are added, and the solution again evaporated, to destroy the excess of nitric acid. The solution is evaporated very nearly, but not quite, to dryness, a few drops of water are added, and the mixture warmed, and when the chloride of silver is settled a drop of solution of stannous chloride is allowed to fall down the side of the tube into the liquid, when the characteristic gold reaction is obtained. This experiment is delicate, and requires some care. For the laboratory method I. is much the easier and quicker of the two; but it is conceivable that method II. might be practically applied to the exploitation of the gold in sea-water, which might be received at high water in large tanks, and emptied at low water, the chloride of barium solution being meanwhile used, and the precipitate left in the tank taken out from time to time.*

III. The method that I give last was that whereby I first obtained evidence of the presence of gold in sea-water; but this method is open to objection, as being more troublesome than the preceding methods. To at least a litre of sea-water, contained in a stoppered bottle, a few grammes of ferrous sulphate are added, and after two or three days some solution of stannous chloride, followed by solution of mercuric chloride, taking care that the latter is added in such proportion that the water is still capable of separating mercury from more solution of mercuric chloride. Neither the precipitates caused by ferrous sulphate nor

by stannous chloride, in sea-water, carry down with them more than a small fraction of the gold present in sea-water; but when the mercuric chloride is added to the water already containing stannous chloride, mercury is precipitated in the liquid, and, as it subsides, carries down with it both gold and silver as an amalgam. The ferrous sulphate may be dispensed with, but then a larger proportion of stannous chloride must be used, and this oxidises so rapidly in sea-water that there is danger of re-solution of its precipitated gold by iodine, as mentioned at the beginning of this paper. The precipitate, if tin and mercury salts only have been used, may be ignited, and assayed in the usual way, and the bead obtained treated as described under II. The assay is, however, troublesome, owing to the large proportion of tin oxide to be treated. But if the precipitate contains iron oxide, the usual method of assay will fail, because during the process of smelting, iron oxide is reduced to the metallic state, even at a low red heat; and the spongy iron locks up the gold and silver away from the lead. Hence, in assaying substances containing much iron oxides, it is necessary, as far as possible, to prevent reduction of the iron by using only borax as the flux, and that in proportion large enough to hold the iron oxide in complete solution. The oxidating and not the reducing flame of the blowpipe must be used upon the assay.*

The reagents used in all these experiments were not only severely tested separately as to freedom from the precious metals, but in each set of experiments on the sea-water, entirely correspondent experiments were made upon rain-water, always with negative results.

I have referred to the solvent action of very dilute solutions of iodine upon gold. The following experiment illustrates this action. A little precipitated gold was added to strong hydriodic acid, slightly coloured by iodine but otherwise quite pure. The acid quickly became opaque. A drop or two of the solution added to a rather strong solution of stannous chloride in a test-glass immediately caused precipitation of purple-of-cassius, the supernatant liquid being colourless, and remaining so on addition of more tin solution. After a few days' exposure, the liquid smelt of iodine; and then addition of more tin salt caused instant separation of purple precipitate;—proving that the iodine liberated had dissolved some of the precipitated gold. After another day or two of exposure, gold was again in solution, and was precipitated by further addition of tin salt, and this was repeated several times; and evidently the re-solution of the gold would have gone on indefinitely after successive precipitations.

As gold is very readily reduced from highly dilute solution by the action of organic matter and of sun-light, it was important to ascertain wherein sea-water differed from ordinary water in its action on gold, or, rather, wherein lay its power to retain gold in solution in presence of organic matter. This power was proved to reside in the iodate of calcium present in sea-water by the follow-

* The precipitation of gold from sea-water by chloride of barium seems scarcely explicable, unless by supposing the gold to be present in the sea-water as an aurate, so as to be thrown down as aurate of barium. This view has much in its favour, and is greatly supported by the fact that if oxalic acid is added to sea-water some time before the addition of chloride of barium, it is scarcely possible to detect gold in the precipitate formed. And this is easily to be understood, since oxalic acid reduces all gold salts, and in so dilute a liquid—that is, a liquid in which any gold reduced is so finely divided—any precipitation of such gold, unless under the conditions described in the methods I. and III., could not be expected to take place.

* Some years ago, having occasion to make a great number of assays for the precious metals in specimens taken from the mountains of Reumammawr, in North Wales, I was greatly puzzled by the conflicting results obtained with the same reagents, but under different modes of working. Specimens smelted before the blowpipe always gave much higher results than those that were treated in crucibles. For in the former case I used only borax as a flux, and in the latter, to make the mixture more fusible, and also to ensure a good button of lead, I used, besides borax, carbonate of sodium or of potassium and charcoal powder. Nevertheless, even in the latter case, beads of auriferous silver containing also platinum were always obtained; for the proportion of iron oxides contained in the mineral was not large enough entirely to prevent the solvent action of the lead upon the precious metals. But more recently on assaying a series of red hematite ores found in the Isle of Man, I obtained from some specimens treated before the blowpipe, with a good proportion of borax, as much as 16 ozs. silver to the ton; while the same specimens smelted in crucibles as described, left a spongy mass of iron, and the lead button contained no silver. I repeated the experiments often enough to leave no doubt respecting the cause of these discrepancies being that referred to in the text. I also sent samples of these ores, containing from 4 to 16 ozs. silver to the ton, to eminent assayers, who informed me that they contained no trace of the precious metal.

ing direct experiment.* A drop of gold solution was added to about 400 c.c. of rain-water, and the solution was divided into two equal parts, to one of which a tenth of its bulk of solution of iodate of calcium containing 1 part iodate to 1000 of water was added. A drop of the same gold solution was added to 400 c.c. sea-water, and another drop to a corresponding quantity of iodate of calcium solution. The beakers containing the four solutions were placed, uncovered, in sun-light. All the solutions except that of sea-water became perceptibly coloured after a few hours, and next day were distinctly ruby-coloured, the sea-water remaining colourless. After another day or two, however, all had become nearly colourless, except the pure solution of gold, which remained permanently coloured. The disappearance of the colouration could only arise from solution of the precipitated gold, since subsidence was out of the question. Ruby liquids so dilute as these I have found not to lose colour by subsidence for months. Many similar experiments have been made under varied circumstances, all showing that solution of iodate of calcium has absolutely no solvent action on gold, nor even the power to prevent its reduction from solution. But so soon as the iodate itself undergoes partial decomposition under the influence of putrescible matter, iodine is liberated, and gold, if present, is dissolved.

REPORT UPON THE CHEMICAL AND ALLIED PRODUCTS SHOWN IN THE DUBLIN EXHIBITION.

THE Dublin Exhibition so far has been a success, mainly owing to the fine Art Collection of pictures, and what is termed the Loan Collection. There is not much novelty as regards the chemical and other products shown, but what is there is excellent in quality. They are all British and Irish exhibitions, with the addition of a few Colonial ones. It is generally supposed that the Exhibition will close at the end of November, although this has not been officially announced. The following are the Exhibitors who will probably interest our readers.

Messrs. J. C. and J. Field, London.—This celebrated firm exhibits many articles of interest, particularly in the candle line. They are also probably the exhibitors of the greatest novelty in this branch of manufacture, namely the ozokerite candles. This fossil resin was first mentioned by Meyer, who discovered it in Moldavia in connection with coal and rock-salt. The source of the candles made by Messrs. Field is a product from the Carpathian Mountains, which seems to have been first submitted by Dr. Letheby to the notice of that firm in 1868. They seem to have surmounted all the practical difficulties incident to the purification of this unpromising brown substance, and have produced the most beautiful candles in appearance

* I do not by this mean that solution of iodate of calcium has any power to dissolve gold, or to retain it in solution when dissolved by any direct action. But, as has been shown in former papers, putrescible organic matter causes liberation of iodine in a neutral or slightly alkaline solution of iodate of calcium, and the iodine thus liberated continuously dissolves the gold that is being continuously precipitated, if such an expression referring to nascent conditions may be permitted. It is clear from the experiments given in the text, that organic matter is capable of precipitating gold earlier than the stage at which that balance of destructive and conservative forces always at issue between organised and inorganic matter arrives at which iodate of calcium begins to decompose, such decomposition leading the liberation of iodine, which, as shown, reacts upon any precipitated gold to dissolve it. From these premises we may easily see how, although sea-water must always retain some gold in solution, it may yet, under circumstances not only conceivable, but such as must necessarily occur in regions where the passage of organic matter to a state of putrescence is too rapid for the formative power of the iodate of calcium in sea-water to keep pace with it, cause precipitation of gold. Hence it is, as it appears to me, that gold-fields are found richer in tropical regions where decomposition goes on at a quick rate, than in colder regions where the re-forming power of iodate of calcium can exercise a more powerful solvent action upon the gold which sea-water has extracted from the original material of which the earth is composed.

which have yet been made. The characteristics of the crude ozokerite which is shown is as follows:—Its colour is brown, with a wax-like lustre when burning. Its odour is of the aromatic hydrocarbons. It is said to have a sp. gr. of 0.94, and melts 66° C. It distils without decomposition, and is not altered by strong acids. It slightly differs in chemical and physical properties according to the source from whence it is derived, and the above description applies more to the specimens of crude ozokerite shown by Messrs. Field and Co., and examined by the writer. It is, when purified, a variety of paraffine having the following composition:—

Carbon	85.75
Hydrogen	15.15
	100.9

Nothing can exceed the beauty of the candles as made by Messrs. Field and Co. from this unpromising looking substance; and it would appear from the report of Dr. Letheby, that they exceed any other yet introduced as regards illuminating power. He gives the number of grains required to give the light of 1000 grains of the best spermaceti candles as follows:—

Ozokerite candles	754
Various paraffine candles	798 to 891
Sperm candles	1000
Wax candles	1150

As it has a very high melting-point; it does not bend or soften; it is, in fact, a much harder material than ordinary paraffine. It would be out of place to deal with Messrs. Field's numerous specialities in a periodical like the *CHEMICAL NEWS*; they are ingenious, and make up one of the most interesting cases in the Exhibition. For instance, the tinting of paraffine candles mauve and magenta with aniline colours is a great improvement upon the old opaque mineral colours. As regards paraffine candles, this firm claims priority over all others in the introduction of them to the public. They say, "We claim the merit of being the first in the English trade to manufacture for general sale, paraffine candles, and to have mainly contributed to their success, &c." Messrs. Wm. Brown and Co., of Glasgow, were actually the first makers in 1855; but to show the great stride that this article of industry has made, we may mention that in the letter addressed by Messrs. Field to the Secretary of the Exhibition of 1862, they state that whilst the candle was introduced at a price of 2s. 4d., and with a consumption of 3 to 4 cwt. weekly, it was at this time sold for 1s. 5d. This firm used 3 to 4 tons weekly; and in 1867 the total English make was some 2000 tons annually.

Messrs. Price and Co.—There is nothing particularly new about the case of this firm. It is certainly very handsome, and the contents excellent, but it is a mere reiteration in saying this of the articles turned out by the said firm. Added to which, all chemists must look at Messrs. Price and Co. with respect as the originators of pure glycerine, and the promulgators of a great chemical fact. Although distilled glycerine is now extensively manufactured abroad, the originators hold the palm as regards quality. This is mainly due to the fact of its great freedom from acrid products of distillation, which give a disagreeable odour to the glycerine if nothing worse. Glycerine can be, and frequently is, re-distilled by the aid of superheated steam. Very inferior glycerine is now in the market, but its genuineness is so easy of detection, that we are surprised to find such inferior qualities are sold at a high price. Pure glycerine should not give a white precipitate with nitrate of silver, and the resulting mixture should not deposit a precipitate on exposing it to the sun's rays. It should volatilise on heating a small quantity on a platinum foil without leaving a carbonaceous residue; and it should be quite destitute of odour. The "solidified glycerine" is a soap which is stated to consist of 25 per cent of pure glycerine.

Mr. John G. Rathborne, Dublin.—One of the most important Irish exhibitors is Mr. Rathborne, the contents of whose case are *bona fide* specimens of home manufacture. He is a wax-bleacher, and is one of the few firms from whom you can procure pure white wax; although the public have been educated to prefer the prettier article which is now sold under the name of *cera alba*. This house also works paraffine, but its chief interest is the refining of sperm oil and the manufacture of spermaceti. The head-matter of the sperm whale is a semi-crystalline mass of a very dirty and offensive appearance. It is separated into two distinct portions, the fluid, or sperm oil is clarified, and extensively used for lubricating and illuminating purposes. On its freedom from the crystalline portion mainly depends its commercial value; and so well is this understood that certain seasons of the year are considered preferable to others for its manufacture. The crystalline solid portion, or cetin, $C_{32}H_{64}O_2$, when purified by pressure and treated with alkalis, constitutes the spermaceti of commerce, which differs considerably, and more frequently than ordinary observers would imagine, owing to the variable quantities of sperm oil still remaining. The specimens of spermaceti shown (both crystallised and manufactured into other forms) are certainly the finest we ever saw as regards purity in this respect, which is mainly gained by hydraulic pressure.

Messrs. C. Ogleby and Co, London, exhibit candles and other products.

Newry Salt Company.—Different varieties of salt are shown by this Company; they are procured from rock-salt, and are beautifully pure.

Cantrill and, Cochrane, Dublin, show mineral and medicinal waters.

Messrs. McMasters, Hodgson, and Co., Dublin, are expressers of linseed oils, and rape oils. They also show the respective cakes, and some other proprietary articles, such as fluid annatto, all excellent preparations.

Messrs. Boileau and Boyd, Dublin.—The case belonging to this firm contains an interesting collection of chemicals, some of them rare. They have been arranged most artistically; and we noticed one very fine specimen of them made by crystallisation from damaged tea. It is used in medicine as a tonic and stimulant in doses of 1 to 5 grains.

The starch exhibitors are not very numerous, but are remarkably good, particularly the Irish manufacturers. It is perhaps, not generally known that Ireland is celebrated for its wheat-starch amongst the trade. With the general public rice has supplanted wheat-starch, owing to the fact that the outer envelope of the granules is more easily broken, and the starch can be made without boiling. Such, however, is not the case with the wheat granules, which require boiling to make the starch. It, however, possesses remarkable stiffening properties, which makes it invaluable for technical purposes. Thus whilst the rice-starch is used by the public, the wheat-starch is used by the Manchester houses.

The exhibitors of starch are as follows:—

J. and J. Colman, London.—Laundry starch prepared from rice, and also rice-starch prepared for dietetic purposes under the name of "Corn Flour."

Charles Cooney and Son, Dublin.—Laundry starch prepared from wheat.

John Kelly, Gaigne.—Rice and wheat-starch for laundry purposes; very good.

Alex. Crawford and Son, Belfast.—Wheat-starch for laundry purposes, beautifully white. Wheat-starch prepared for dietetic purposes under the name of Irish corn flour. In speaking of their preparations they make the following remarks:—

The *Snow-white Starch* is a special manufacture of the firm remarkable for its beautiful colour, its great purity and strength; and is now used by the principal bleachers and finishers in the kingdom in the preparation of the finest goods. It is made from wheat alone, and retains its stiffening power for any length of time. It is supplied

to the Royal Laundry, and gained the gold medal, London, 1870.

The *Irish Corn Flour* is a novelty in this line, being also made from wheat, and therefore possessing the many advantages of that cereal over its competitors rice, Indian corn, and sago; from which the previous corn flours have been made. It is a beautiful white colour, is highly commended for its flavour and fresh pleasant taste, it has great nourishing power, and is adapted to every variety of table use.

The mining exhibitors are not numerous, but are interesting. The first case in importance as well as show, is that of the—

Mining Company of Ireland.—This company has generally been a prosperous one, but under the very peculiar abnormal circumstances attending our coal supplies, we have no doubt that it will with the assistance of Mr. Harold, and their efficient staff of officers, be able to realise a rich harvest. All the works and property of this Company were, some years since (when the writer visited them), an honour to the country as illustrating the manner in which large manufacturing operations might be conducted in a cleanly, methodical, yet in an effective manner. Their lead and silver mines are situated at Glendalough, at the end of the valley which contains the celebrated ruins known as the "seven churches." One entrance to the old mine is about one-third of the way up the mountain. The mountain is bored right through, so that the levels go from one valley to the other. This old working is eighty fathoms deep (480 feet); and besides this they are now rapidly piercing the mountain for new workings. It has been calculated that to raise 1800 tons of dressed lead-ore fit for the market, 46,000 tons of ore are broken by the miner. The rejected stuff is blend, fluor-spar, quartz, and calx-spar. None of these are made available for the market. Very rare minerals have been found in these valleys. Gold, metallic silver, witherite, heavy spar, carbonate of lead. Blend is found in large quantities, but is not worked. About 1.3 per cent of the whole of the lead ore raised in the world is procured from this mine. Ireland yields also about 2.4 per cent of the whole of the silver raised in the world, or about £3850 per annum. The silver is procured by Patterson's process from the silver-lead, which is manipulated at the works of the Company situated at Ballycorus. The lead is converted into pig, sheet, shot, and pipe. They also procure litharge in the refining of the silver, red-lead (manufactured), and arsenic, which sublimes during the smelting of the lead, also antimony. Lead is extensively procured for type-founders, and shot. One of the most important points in connection with the Mining Company of Ireland, however, are their collieries.

The very important question of the price of coal and its supply will probably be ultimately and mainly regulated by Ireland; at any rate as regards its present abnormal inflated condition. The resources of the Irish coal were never thoroughly appreciated, but the writer has no hesitation in saying that the already known or worked mines are sufficient to compete with English coal, if enough energy and capital were only invested in them. Again, the behaviour of the Irish Railway is suicidal to the extension of this branch of industry. Let us take this Company alone. They are working at the present moment the "Bonlea," "Ballinastick," "Coalbrook," "Earlshill," and "Foillacamin" collieries. They are situated in the county of Tipperary. At the present moment they raise annually 50,000 tons, 45,000 tons of which are culm. Besides this, at their collieries at Cork, they raise annually 10,000 tons. It is chiefly anthracite of the very best quality, containing as much as 96 per cent of carbon: it may, in fact, be practically viewed as pure carbon; and is so much valued for some special purposes, such as malting, that 32s. are eagerly paid in Dublin for this coal. It is, although a flameless coal, valuable for steam purposes. We have been credibly informed that for the carriage of this coal, 2s. per ton is charged from

Limerick Junction to the town of Tipperary, a distance of 2½ miles. How can the resources of a country be developed in the face of such restrictions? There is certainly something here that requires explanation. The culm is used chiefly in lime-burning, for which it is particularly suited. Anthracite requires a great draught, but is one of the most valuable fuels we possess, both as regards the intensity of heat produced, and its freedom from sulphur. From Berthier's experiments on the reduction of oxide of lead, we find that anthracite stands very high; yet the sample he experimented upon was not equal to the Irish in quality (*viz.*, Pennsylvania). Wigan cannel produces 28½ parts of lead; Newcastle 30½; Glasgow 24½, and anthracite 30½.

General Mining Company of Ireland, Dublin.—Calamine and oxide of zinc are shown in all their stages of manufacture. This Company possesses at the silver mines in Tipperary the largest deposit of calamine in the United Kingdom; and they manufacture their oxide directly from the ore. The oxide is generally made from spelter. By their process, which is a patent, the Company can make oxide very cheaply, but as it is made directly from the ore the resulting oxide always contains lead, which vitiates to a certain extent its value as a pigment when made by this process. The mining Company are anxious to prevent this by some modification of their process, because if such a change could be brought about the spelter oxide could not compete with it in price. They also show caustic soda made by a patent process in which the inferior brands of oxide are utilised for the production of this article.

This latter process is one which the above named Company are now experimentally determining the merits of. The patentee is a Mr. Crockford.

Connoree Mining Company, Dublin.—Pyrites and copper ores from their mines in Wicklow, &c., and specimens of copper by precipitation. Most of the ingots of gold got in this country have been found in the workings of this Company.

The Geological Survey of Ireland.—The geological maps of Ireland, published by the survey.

Greenagh Colliery, Dungannon.—Specimen of cannel coal, Coal Island, Dungannon. Used in the manufacture of gas, and marked 358. at colliery.

Val de Travers Company.—Specimens of natural asphaltes used in the pavements laid by this Company.

Messrs. Millard and Robinson, Dublin.—There is nothing particularly novel in the way of photographic processes exhibited, if we except some beautiful specimens shown by Messrs. Millard and Robinson. The following seems to be the *modus operandi* by which these excellent results are obtained. An ordinary silver print upon albumenised paper is taken, and the minute defects are painted out with the ordinary tube oil colour thinned with turpentine only. When dry, it is immersed for 30 minutes in water, so as to thoroughly soften the paper, and finally in water at 65° C. A plate of glass, which should be scrupulously clean, is warmed to about 90°, and a solution of Nelson's transparent gelatine is poured over the surface of the glass quickly and so as not to chill the gelatine, and the print is lifted from the warm water and laid face downwards upon the gelatine solution. It must then be carefully and dexterously manipulated, so as to press the print in close contact with the glass, and to expel the superfluous gelatine solution. All air bubbles must be excluded. If a flat plate of glass is used the manipulation will be easy, but by preference convex, or oval convex, or lunette glasses give much better effects. The gelatine solution is made by macerating the transparent gelatine for 12 hours in cold distilled water, pouring off the superfluous fluid and applying heat to melt the gelatine, when it will be found to have just absorbed the requisite quantity and to dissolve thoroughly. It is strained through fine muslin, and is then ready for use. Simple as this process may seem, the effects must be seen to be appreciated. Thus the details in the deep shadows will be brought out in a "fixe" which would not be visible in the ordinary

print. Mr. Robinson, who has introduced this process, also claims, for the photographs thus treated, permanency. He says, "Some idea of the effects of this method of treating photographs may be obtained by taking a photograph and sizing one half, and comparing the effect produced with the unvarnished half. The glass replaces the varnish, and it is evident that no varnish can compare with the glass in the qualities which make, or give, value to a varnish."

The other exhibitors who might possess an interest for the readers of the CHEMICAL NEWS, are as follows:—**Piston Freezing Company, London.**—Patent freezing machines, seltzogens, and other apparatus.

J. Spencer and Son, Dublin.—Jellet's saccharometer (fully described in the CHEMICAL NEWS, vol. xi., p. 294), and other philosophical instruments.

Dublin Glass Bottle Company, North Lotts, Dublin.—Specimens of glass in various stages of vitrification, and bottles in all their stages of manufacture.

Walker, Campbell, and Company, Liverpool.—Hains's patent lead encased block-tin pipe. The proprietors of this pipe state that they have succeeded in combining the two metals, tin and lead, in such a way as to render them in the form of a pipe perfectly homogeneous, the result of this combination being, that the pipe possesses all the ductability and pliability of the lead with the innocuous nature and tenacity of the tin. They also say that, although the cost per ton is double that of the ordinary lead-pipe, the weight per yard required for a given pressure is only half, therefore the cost is the same. Thus Hains's patent pipe by experiment was ½ inch inside diameter, the weight per yard 4·017, the extension was 13·6 per cent, and the bursting pressure was 1859 lbs. per square inch. With common lead-pipe the inside diameter was ½ inch, the weight per yard was 7·13 lbs., the extension was 9·7 per cent, and the bursting pressure per square inch 1579. Dr. Lankester said he had submitted these pipes to the action of distilled water, Thames, and other waters, and neither lead nor tin could be detected in the water. Also acid decoctions seem to be without action upon the tin.

Messrs. Bryan Corcoran, Witt, and Co., Mark Lane, London.—Specimens of wire-weaving for sifting, &c., Iron gauze, containing 10,000 holes to the inch, and brass wire gauze 150 holes to the inch are shown.

W. S. Rumsey, London.—Various polishing and other pastes.

Bermondsey Indian-Rubber Works, London.—Indian-rubber in all its stages and in the raw state.

D. Tallerman, 90, Cannon Street, London.—Australian preserved meats, meat extracts, &c.

James Tennant, jun., Smithfield.—Specimens of minerals from Nova Scotia, St. Helena, Algoa Bay, and South Africa. Collected by the exhibitor during his travels.

Anti-Adulteration Society, Dublin.—Products used in adulterating. Adulterated manures, &c.

Thomas G. White, Dublin.—Charcoal, pyro-lignite, acetate of lime, acetate of soda, acetic acid, &c., from the destructive distillation of Irish wood.

John Somerville, Gas Company, Dublin.—These are a very complete series of products illustrative of the destructive distillation of coal in the process of gas making. Mr. Somerville is the engineer to the extensive gas works in this city, and besides all the direct products of distillation, such as carbolic acid, benzoin, toluol, &c., he shows all their derivatives, including the anthracene derivatives and the aniline colours.

Messrs. Berger Spence and Co., Manchester.—This firm exhibits a beautiful crystal of alum; the specimen being made from coal shale, pyrites, and refuse from the ammoniacal gas works. This fine crystal exhibits a very faint amethyst tinge.

Messrs. Boyd and Alexander, Dublin.—Chloride of lime (38 per cent), commercial acid, manures, &c.; a good collection.

Marine Salts Company, Dublin and Galway.—A very excellent collection, illustrative of the products manu-

factured by this Company from sea-weeds collected upon the west coast of Ireland. They exhibit iodine, bromine, and the accompanying salts; also the principal sea-weeds from which the kelp is derived with their relative value in iodine given—e.g., *Laminaria digitata*, *Laminaria saccharina*, rich in iodine; *Fucus serratus*, poor in iodine.

Dublin and Wicklow Manure Company.—Good specimens of commercial acids, manures, &c.

Messrs. Bewley and Draper.—Mineral waters and dichroic ink. The preparations of this firm are so well known and appreciated in Ireland that it is superfluous to dwell upon them.

Messrs. Yeates and Son, Dublin.—This firm shows astronomical telescopes and spectroscopic apparatus. The compound prisms for the latter are very beautifully made.

Amongst the soap makers there are two that require special mention.

Messrs. Holt, Nerwich, and Co., Vauxhall Walk, Lambeth, London, exhibit pure oil soaps for technical purposes. The light oil soaps are made for using with silks, poplins, and woollen goods. The black oil soaps are half the price, but of course can only be used for black goods. The great advantage claimed for these soaps are that they never congeal, and may be used indifferently in hard, soft, and salt waters. The soaps were examined by the reporter, and found to be genuine cheap soaps perfectly saponified. The amount of causticity was slight (= 1.8 per cent soda). The specimen was almost entirely soluble in spirit, the residue being only 1.6 per cent, whilst the amount of moisture was comparatively low for a new specimen of soap, viz. 1.8 per cent. Such soaps are no doubt valuable adjuncts to the trade.

Messrs. Fred. Lewis, and Co., Fleet Street, Dublin, are worthy of more than simply their names appearing as soap and perfume makers, from the fact that they manufacture largely much of the exported soaps that go to our Colonies. They also, some time since, contradicted and exposed a statement that was going the round of the scientific world, that the perfumed soaps, such as Windsor, &c., were made from horse-green. In the higher class of perfumed soaps, the actual cost of the soaps used (which are generally two) is a secondary consideration. They show a pillar of perfumed soap which is probably the largest ever cast in one piece; and show beautiful samples of curd and white Windsor. The soaps shown by Messrs. Lewis, and Co. are perfectly neutral.

British Seaweed Company, Dalmuir, Glasgow.—Mr. Edward Stanford's well-known process for manufacturing the products of seaweed are well known, and the importance of his patent must be felt with the present high price of iodine. The remarkably large produce of iodine must give them a decided advantage. The increased produce is due to the non-volatilisation of the iodides, such as occurs during the ordinary process of the burning of the kelp. A series illustrating their process is given in the case, also one showing, the carbon closet system, which has been fully described in the CHEMICAL NEWS, vol. xxv., p. 75. The method of excretal removal is a modification of the earth closet system, in which some form of carbon is substituted for earth. By the use of charcoal the amount of deodoriser required is reduced to less than a fourth as compared with earth, and a constant supply is secured. The system is being adopted by many of the large public works.

ON MEASURING TEMPERATURES BY ELECTRICITY.*

By C. WILLIAM SIEMENS, D.C.L., F.R.S., M.R.I.

(Concluded from p. 154).

ALTHOUGH I have explained that, by means of a differential galvanometer and a variable resistance (constituting in effect a Wheatstone bridge arrangement), the increasing

resistance of the platinum spiral may be measured, it was found that the use of a delicate galvanometer is attended with considerable practical difficulty in iron-works and other rough places where it is important to measure elevated temperatures, or on board ship for measuring deep sea temperatures. I was therefore induced to seek the same result by the conception of an instrument which is independent in its action from tremulous motion, or from magnetic disturbance caused by moving masses of iron, and which requires no careful adjustment or special skill on the part of the operator. This instrument is represented by Fig. 4, and may be termed a chemical resistance measurer or "differential voltmeter." The immortal Faraday has proved that the decomposition of water in a voltameter expressed by the volumes of gases V,

FIG. 4.

is proportionate in the unit of time to the intensity, I , of the decomposing current, or that—

$$I = \frac{V}{T}.$$

According to Ohm's general law, the intensity, I , is governed by the electro-motive force, E , and inversely by the resistance, R ; or it is—

$$I = \frac{E}{R}.$$

It is therefore—

$$\frac{V}{T} = \frac{E}{R} \text{ or } V = \frac{ET}{R};$$

or the volume, V , would give a correct measure of the electrical resistance, R , if only the electro-motive force, E , and time, T , were known and constant quantities. But the electro-motive force of a battery is very variable; it is influenced by polarisation of the electrodes, by temperature, and the strength and purity of the acid employed. The volume of gases obtained is influenced, moreover, by the atmospheric pressure, and it is extremely difficult to make time observations correctly. It occurred to me, however, that these uncertain elements might be entirely eliminated in combining two similar voltameters in such a manner that the current of the same battery was divided between the two, the one branch comprising the unknown resistance to be measured, and the other a known and constant resistance. The volume of gas, V_1 , produced in

* Read before the Royal Institution of Great Britain.

Edited by the Rev. WILLIAM HIGGS, M.A., sometime Assistant to Professor
Sir CHARLES WHEATSTONE, D.C.L., F.R.S.

THE importance of the Science of Telegraphy is so universally admitted, that it is remarkable there does not exist in England a Journal specially devoted to a Science which has tended so materially to increase our national wealth and well-being. The Proceedings of the Learned Societies, though containing an account of the Scientific Progress of Electricity, are naturally precluded from considering its Commercial aspects and relations. To supply this deficiency THE TELEGRAPHIC JOURNAL is added to the daily-increasing list of Periodical Scientific Literature. The arrangement of this Journal will be as follows:—

LEADING ARTICLES devoted to subjects relating to Telegraphy or cognate Electrical Science, which are of immediate interest and importance.

ORIGINAL PAPERS from the pen of Eminent Electricians and Scientists.

ABSTRACTS of the PROCEEDINGS OF SCIENTIFIC SOCIETIES.

REVIEWS of SCIENTIFIC BOOKS.

ABSTRACTS or a RESUMÉ of all Memoirs upon Electrical Science which have appeared in FOREIGN JOURNALS during the month.

SHARE-LISTS and CITY-NOTES.

A STUDENTS' COLUMN, comprising Didactic Articles in Telegraphy and Electricity.

EDITORIAL NOTES of Appointments in the Service, and of Passing Events.

A List of the LETTERS PATENT Applied for and Granted.

The Journal will also be a medium of intercourse between Telegraphists; a channel through which OPERATORS can declare their wants; and a Guide to the Investor and those interested in the Commercial Progress of the Science or of any particular project. In dealing with questions of Administration it will be the aim of the Editors to secure full independence of thought and action.

THE TELEGRAPHIC JOURNAL, as a REVIEW OF ELECTRICAL SCIENCE, will contain Articles of value to the Electrotyper, Electroplater, and Amateur Experimentalist.

Published on the 15th of each month. Price 6d., or 6s. per annum post free, payable in advance.

London: HENRY GILLMAN, Boy Court, Ludgate Hill, E.C.

this second voltmeter, having a resistance, R^1 , in circuit, would be expressed by—

$$V^1 = \frac{ET}{R^1},$$

and we should have the proportion of—

$$V : V^1 = \frac{ET}{R} : \frac{ET}{R^1};$$

or E and T , being the same in both cases, may be struck out, and the expression will assume the simple form—

$$V : V^1 = R^1 \div R.$$

The constant resistance, R , of the one circuit being known, it follows that the unknown resistance, R^1 , is expressed by—

$$\frac{R^1}{V^1};$$

that is to say, by a constant multiplied by the proportion of gas produced in the two voltmeters irrespective of time, or strength of battery, or temperature, or the state of the barometer.

The resistance, R and R^1 , are composed each of two

prising the permanent resistance, R , and the leading wires up to the pyrometer, and the other the leading wires and the pyrometer coil. If the resistance of the pyrometer coil should be equal to the permanent resistance, R , the $R^1 + y$ will be equal to $R + y$, and therefore $V = V^1$, but as the resistances differ, so will the volumes. Necessary conditions are: that both reservoirs are filled with the same standard solution of pure water with about 10 per cent of sulphuric acid, that all the electrodes are of the same form and size, and that their polarity is reversed frequently during the progress of each observation, in order to avoid unequal polarisation. With these precautions, which involve no particular skill or knowledge of electrical observation on the part of the operator, very accurate results are obtained; but in order not to incur considerable error of observation, it is advisable to continue the current, reversing the same say twice, until at least forty divisions of gases are produced in the least activated tube, which operation will occupy from two to three minutes; if a battery of from 4 to 6 Daniell elements is employed. The volumes, V and V^1 , being noted, after having allowed half a minute for the gases to collect after the current has ceased, the weighted cushions upon the tubes are raised,

FIG. 5.

resistances, viz., that of the principal coils, which we may term R or R^1 , and of the voltmeter and leading wires, which is the same in both cases, and may be expressed by y . The expression should therefore be written as follows:—

$$V : V^1 = R^1 + y^1 : R + y,$$

R^1 being the unknown quantity.

The mechanical arrangement of the instrument will be understood from the diagram, Fig. 4; and the whole arrangement of the pyrometer, with its leading wire and resistance measurer, from the general view given in Fig. 5. The voltametric resistance measurer consists of two calibrated vertical tubes of glass of about 3 m.m. diameter, which are fixed upon a scale showing arbitrary, but equal divisions. The upper ends of the tubes are closed by small cushions of india-rubber pressed down upon the openings by means of weighted levers, whereas the lower portions of the tubes are widened out and closed by plugs of wood, through which the electrodes in the form of pointed platinum wires penetrate to the depth of about 25 m.m. into the widened portions of the tubes. By a side branch, the widened portion of each vertical tube communicates, by means of an india-rubber connecting-pipe, to a little glass reservoir containing acidulated water, and supported in a vertical slide. In raising the weighted cushions, closing the upper ends of the vertical tubes, and in adjusting the position of the small reservoirs, the acidulated water will rise in both tubes to the zero line of the scale. In turning a button in front of the tubes, the battery current is passed through both pairs of electrodes, the one circuit com-

in order to allow the gases to escape, when the water levels will immediately return to their zero position, to make ready for another observation. By inserting the observed values for V and V^1 into the expression above given, the unknown resistance, R^1 , can be easily calculated; but, in order to facilitate the use of the instrument, I have prepared a Table which gives at a glance the resistance due to any two observed volumes, the volumes V governing the vertical, V^1 the horizontal columns, and the resistance being read off at the point of intersection. At each point of intersection the resistance is marked in black, and the corresponding temperature in red ink.

It now remains only to be shown what is the relation between the resistance and temperature in heating a platinum wire. The researches of Dr. Matthiessen, who has made the latest investigations on the effect of temperature upon electrical resistance, are restricted to the narrow range of temperatures between 0° and 100° C., nor do they comprise platinum. He adopted the following general expression for the pure metals:—

$$R_t = \frac{R_0}{1 + \alpha t + \gamma t^2},$$

which, in determining the specific values of α and γ for each metal, gives a close agreement with observation between the narrow limits indicated, but is wholly inapplicable for temperatures exceeding 200° C., when the value t^2 commences to predominate and to produce absurd values for R_t .

It was necessary for my purpose to undertake a series

of elaborate experiments with a view of finding a ratio of general application. Coils of thin wire, of platinum, iron, copper, and some other metals, were gradually heated and cooled in metallic chambers containing the bulbs of mercury thermometers, and for higher temperatures of air thermometers, and the electrical resistances were carefully noted. The progressive increase of electrical resistance was thus compared directly with the increasing volume of a permanent gas (carefully dried) between the limits of zero and 470° C. and a ratio established, which is represented by the formula

$$R_t = aT\frac{1}{2} + \beta T + \gamma,$$

in which T signifies total temperature counting from the absolute zero, and α , β and γ specific coefficients for each metal. According to this formula the electrical resistance is a constant at the absolute zero, and progresses in a ratio represented graphically by a tipped-up parabola, approaching more and more toward a uniform ratio at elevated temperatures. Although the comparison with the air thermometer could only be carried up to 470° C., the general correctness of the ratio of increase just stated has been verified by indirect means in measuring progressive heats, and by comparison with the platinum ball pyrometer.

It is important to mention here that great care must be exercised in the selection of the platinum wire for the measuring spiral, platinum wire having been met with conducting only 4.7 times better than mercury at zero, C., and others; conducting 8.2 times better than mercury, although both samples had been supplied by the same eminent makers, Messrs. Johnson and Matthey. The abnormal electrical resistance of some platinum wire is due chiefly to the admixture of iridium or other metals of the same group, and it appears that the platinum prepared by the old welding process is purer and therefore better suited for electrical purposes than the metal consolidated by fusion in a Deville furnace.

In conclusion, I shall show some working results of the pyrometer in measuring by means of the same protected coil a mixture of ice and water, boiling water, molten lead, and the fire itself by which the lead is melted, the readings produced being 2° C., 98° C., 330° C., and 860° C. respectively. The latter temperature signified a cherry-red heat, as may be judged by the appearance of the tube when withdrawn from the fire. The instrument which I have had the honour to bring before you this evening has already received several useful applications. Through its first application an important telegraph cable was saved from destruction through spontaneous generation of heat. Professor Bolzani, of Kasan, has made some interesting applications of it for recording the temperature at elevated points, and at points below the earth's surface. Mr. Lowthian Bell has used it in his well-known researches on blast-furnace economy; and at several iron works pyrometer tubes are introduced into the heating stoves, and permanently connected with the office, where the heat of each stove can at all times be read off and recorded. These and other applications are sufficiently self-evident, if the soundness of the principles upon which I rely is conceded; but I feel that the shortness of time at my command has hardly enabled me to do more than pass these in review, while endeavouring to demonstrate the results obtained of recording the temperatures of distant or inaccessible places, including furnace temperatures.

ON DYES AND DYE-STUFFS OTHER THAN ANILINE.*

By Dr. F. CRACE CALVERT, F.R.S.

(Concluded from p. 152).

I SHALL now proceed to give you a brief outline of the characteristic differences of the several tannin matters.

* The Cantor Lectures, delivered before the Society of Arts. Revised and communicated by the Author.

Gall-nuts are the most valuable and important of all tannin matters. They are produced by the female of an insect called *Cynips*, which pierces the buds on the young branches of the *Quercus infectoria*, a tree growing especially in the East. There she soon deposits her eggs, and the bud loses its natural growth, and swells out to the size of a hazel-nut, having a green, red, or pink colour. The eggs thus inclosed soon hatch, and the insect undergoes all its metamorphoses until it attains the perfect state, when, if allowed (which is not to the interest of either the gatherer or consumer), it makes a hole and escapes. Good gall-nuts should not be so pierced, and they should be heavy, and of a fresh green colour. If the insect has escaped they are yellow, and are not of nearly so good quality.

In the market, they generally bear the name of the port from which they were shipped. Thus, there are Aleppo gall-nuts, which are considered the best in the market, then the Morea, Smyrna, &c.

The following may be considered as the composition of an average sample of gall-nuts:—

Tannic acid	65.0
Gallic acid	2.0
Ellagic acid	2.0
Luteo-gallic acid	2.0
Chlorophyll and volatile oil	0.7
Brown extractive matter	2.5
Gum	2.5
Starch	2.0
Lignine	10.5
Sugar, albumen, &c., and ash	1.3
Water	11.5

100.0

Gall-nuts are employed to produce blacks on silks, in the preparation for Turkey-red, to produce fast blacks in calico-printing, and, lastly, large quantities are used in the manufacture of pyrogallic acid, the consumption of which, in the present large requirements of photography, must be enormous. We shall see, as we proceed, that gall-nuts are the only available tannin matter for the production of this acid.

An inferior quality of gall-nut is also sold, which is found on the *Quercus*, called *Knoppern*, which grows in Hungary, Styria, Croatia, and Piedmont. It is used in those countries for tanning leather, and in some parts of Germany as a cheap substitute for the Eastern nuts.

Sumach is, as Dr. Stenhouse's researches show, the only substance in which the tannin principles are identical with those of gall-nuts, although in this tannin matter there is a comparatively large quantity of gallic acid. It also contains a soluble yellow principle.

Sumach is found in commerce as a coarse powder obtained by the trituration of the young branches and leaves of several varieties of the family *Terebenthaceae*. The species most cultivated is the *Rhus coriaria*, which is a plant indigenous to Italy, Sicily, France, Spain, and Portugal. The shrub grows to a height of 16 feet in the most arid soils, and is very extensively cultivated in some of those countries. The twigs and leaves are gathered once a year.

Although sumach varies greatly in the amount of tannin it contains, there can be no doubt that from the *Rhus coriaria* is the best, whilst the most inferior comes from the South of France, and is the produce of the *Coriaria myrtifolia*.

In consequence of the powdered state in which sumach is sold, it not only varies greatly in quality, but is often deliberately adulterated with sand, or the leaves of other plants. It is easy to discover the sand, it being only necessary to put some of it in water, when the sand, from its greater specific gravity, readily falls to the bottom of the vessel. I will describe the method of determining the amount of tannic acid later on.

Extract of sumach is sometimes employed in print-works, to produce yellows with acetate of tin, blacks and greys with iron mordants, and dark yellow with sulphate of zinc. It is also used to produce blacks on woollen fabrics, although it does not give as good blacks as gall-nuts. Its principal use, however, is to mordant, either alone or in conjunction with salts of tin, the cotton warps of the mixed fabrics so extensively manufactured in Yorkshire, by which means the cotton takes the same colours as the woollen web, both with vegetable dye-stuffs and those derived from coal-tar.

Sumach is too expensive a tannin matter to be used for the tanning of leather, but it is employed by the currier in the preparation of skins for dyeing with light shades.

Valonia is the acorn-cup of the *Quercus agilops*, which grows in the isles of the Grecian Archipelago and on the coasts of Asia Minor. It is especially employed for tanning leather and adulterating garancine.

Divi-divi is the pod of the *Casalpia coriara*, and is chiefly imported from South America.

Myrobalans, which are largely used for tanning leather and producing blacks on wools, are the dried fruit of the *Terminalia chebula*, and are imported chiefly from Calcutta.

Dr. Stenhouse has shown that the tannin matter of *valonia*, *divi-divi*, *myrobalans*, and oak bark, are not identical with those of gall-nuts and sumach. They do not yield gallic acid when boiled with dilute sulphuric acid, but sugar and some other organic principle.

From the above facts it must be obvious to all who use tannin matters, whether dyers or tanners, that these substances not only vary in value, according to the variety of plant from which they have been obtained and the country whence they are imported, but there are sources of deterioration which cannot be detected by the eye. Thus, for example, if a new sumach be mixed with a comparatively old one, it is impossible to detect the fraud. The only method, therefore, of ascertaining the value of a sample is to determine chemically the amount of tannic acid it contains. This may be done by the following process:—A weighed quantity (say 100 grains) of the substance to be tested is boiled with distilled water, and the decoction run off into a beaker, without filtering. This process is repeated four or five times. A test solution is prepared by dissolving 1 drachm of gelatine in 4 ounces of water, and adding 15 grains of powdered alum to the solution: 155 grains of this solution represent 5 grains of pure tannic acid. The test fluid is carefully dropped into the beaker until, on the falling of a drop upon the surface, the characteristic ring of tannate of gelatine is no longer produced. The quantity of test fluid used is then ascertained, and from this the amount of tannic acid is calculated.

Before passing from this class of tannin substances, there is one that I must mention, which has been used from the most ancient times, in Egypt, Arabia, and other Eastern countries, to dye wool, horse-hair, leather, &c. It is the leaves of the *Lawsonia inermis*, which appears to be the gopher wood of Scripture and the henna of the Egyptians. The leaves are mixed with water, to form a paste of an orange-brown colour. This paste also is employed by the Asiatic ladies to dye the nails of their hands and feet, as well as their ears and hair.

Catechu, *gambier*, and *gum-kino* are the most valuable of the tannin substances, which give a green colouration with per-salts of iron. They are most extensively used to produce a great number of shades, varying from light drabs to dark brown, in cheap dyed cotton goods, such as fustians and corduroys. They are used in calico-printing chiefly to produce browns, in silk dyeing to weight the silk, and in tanning to produce a low class of leather, easily distinguishable from that properly tanned with bark and other matters belonging to the first class, because when used for making shoes it communicates to the stockings a peculiar orange-yellow hue.

For a long time there was much doubt as to the genus of plants from which catechu, gambier, and kino, which resemble each other very closely in their properties, were derived. M. Guibourt, a few years ago, solved the problem. He found that real catechu, or cutch, was obtained from the wood of the palm called *Areca catechu*, and the *Acacia catechu*, whilst gambier is extracted from the leaves of the *Uncaria gambir*, *terra japonica*, belonging to the family *Rubiaceae*, and kino is obtained principally from the *Butea frondosa*, a leguminous plant.

Catechu is found in commerce principally in two states; the best in lumps varying in weight from 80 to 90 lbs., of a dull purple colour, and covered with leaves; the second in masses, more or less covered with sand.

Gambier is imported into this country in the form of small cubes, having a yellowish-brown colour.

Good catechu should not leave, on incineration, more than 4 or 5 per cent of ash. Its aqueous solution should give, with alcohol or gelatine, an abundant white precipitate, with lime and baryta a brown precipitate, with salts of lead and tin a yellow precipitate varying in shade with the salts employed, and with bichromate of potash a brown precipitate. It should also take a decided brown hue with alkalies, and assume a greenish colour with salts of iron.

Catechu, besides naturally varying widely in quality, is freely adulterated with mineral substances, starch, tannin matters, and blood.

I have just stated the amount of ash a good catechu should yield. To ascertain the presence of starch, the sample should be first treated with alcohol, and the insoluble residue boiled with water, which will give a fine blue colouration on the addition of iodine if starch be present. The presence of any ordinary tannin matter in the catechu will modify the green colouration which the latter substance gives with the per-salts of iron. Blood may be detected, if present, by treating the catechu with alcohol, and, after drying the insoluble residue, heating it in a tube, when ammoniacal vapours will be given off, as well as vapours of a most offensive odour.

Catechu is composed of three distinct substances,—first, a tannin matter called *mimo-tannic acid*; second, *catechine*, or *catechinic acid*; and, lastly, a brown colouring matter due to the oxidation of the catechine.

Mimo-tannic acid is prepared by treating pulverised catechu by ether in a displacement apparatus. The ethereal solution leaves, on evaporation, a yellow porous mass of this acid. Bombay catechu yields about 55.5 per cent of *mimo-tannic acid*; that from Bengal, 48.2 per cent; while gambier yields from 36 to 40 per cent.

Catechine, or *catechinic acid*, is obtained by treating with boiling water the residue from catechu, which has yielded its *mimo-tannic acid* to ether. The water on cooling deposits a brown crystalline precipitate, which is re-dissolved in water, and yields with sub-acetate of lead, and the precipitate washed. The lead compound is then suspended in water, and decomposed by sulphuretted hydrogen, when pure catechine remains in solution. Its formula is $C_{10}H_{10}O_4$. It rapidly becomes coloured brown in the presence of air, and an alkali, being, it is said, converted into *japonic acid*, whilst, with alkaline carbonates, it yields *rubinic acid*. It is also converted into japonic acid under the oxidising influence of salts of copper and of bichromate of potash.

If dyers, instead of employing catechu as imported, were to grind it, and wash with cold water, they would obtain an extract which would yield very pure shades of green drabs, while the insoluble residue of catechine would give a great variety of shades of brown. To increase the permanency of catechine colours, the goods dyed with them should be passed through a solution of bichromate of potash, as is usually done for catechu browns.

Dr. Stenhouse has shown that the tannin matters giving a green colouration with per-salts of iron, such as

catechu and elder and larch barks, do not contain a glucoside. The only exception he has found to this rule is willow bark.

PROCEEDINGS OF SOCIETIES.

SCIENTIFIC AND MECHANICAL SOCIETY, MANCHESTER.

At the last monthly meeting of the above Society, which was held on Wednesday, the 4th of September, a resolution was unanimously passed—"That a special committee be appointed to take into consideration the Society's future programme, and to make the necessary arrangements for carrying out the same. This committee to revise the existing or draw up new rules, and organise additional sections to their own (the engineering section), representing the staple industries of the district in all its most important branches, similar to the well-known Société Industrielle de Mulhouse, to consider the advisability of taking immediate steps for the establishment of a Technical Reference Library and Reading Room, and the publication of the Society's proceedings. The mover of the resolution in his remarks said it was hoped there would at least be a section devoted to Technical Chemistry, another to Spinning and Manufacturing, &c., for the coming session, which would begin in November. If we looked upon that eminently useful and authoritative body, the Société Industrielle de Mulhouse, it was difficult to understand that a similar movement should not have been set on foot in such an important centre of industry as Manchester was long ago; but it seemed evident that it simply required a start, it was clear that there was ample scope and an urgent want for such an extension of their Society. He hoped that those gentlemen who mooted the subject in letters published some time ago in the CHEMICAL NEWS would join and co-operate with them.

A committee with full powers was then elected, consisting of Messrs. Von Hohenhausen, Dreyfus (analytical chemists), Hilton (manufacturer), Spriggs, Lynde (mechanical engineers), Tolhausen, Ziffer, Ross (civil engineers), Hacking and Hildebrandt (civil engineers), the hon. sec. of the Society.

This committee held its first sitting on the Wednesday following, and appointed deputations to wait upon gentlemen of influence and practical experience representing chemistry and engineering, and willing to take an active part in their labours.

At the second committee meeting, which was held the following Wednesday, Messrs. Richard L. Messtayer, C.E., and Charles J. Allport, M.E., were added to the committee, and at the last meeting, held last Wednesday, the 25th inst., at the "Trevelyan" Hotel, Messrs. F. Spence (Pendleton Alum Works), John Gilchrist (ditto), Hart (Messrs. Tennants and Co.), Evan, Levinstein, and James N. French, gentlemen engaged in chemical manufacture, attended, and were elected members of the committee, all expressing their conviction that a movement of the kind as contemplated was a great desideratum, and promising their hearty co-operation.

Thus it will be seen that a very important point has been settled: There will be a Chemical Section, and efforts will also be made for the organisation of a technical library and reading room. Arrangements will be made that the sections meet on different days, so that each member of the Society may be able to attend each meeting if he so chooses. It is hoped that after sections may be organised in due course, and those gentlemen desirous to co-operate with the committee or to become members of the Society—the name of which will probably be altered also—are requested to communicate with the hon. sec., 64, Frema Street, Manchester.

CORRESPONDENCE.

NEW PROCESS FOR ANALYSING COMPOUND ETHER.

To the Editor of the Chemical News.

SIR,—Allow me to state in your columns that one of the processes for analysing compound ethers, brought before the British Association at its recent meeting, by Prof. Wanklyn, viz., heating the ethers with an alkali and estimating the amount of alcohol liberated, has already been described by myself as long ago as the year 1867, and will be found fully explained in the *Journal of the Chemical Society* of that year, as also in the work on Wine by Dr. Thudichum and myself.—I am, &c.,

A. DUPRE, Ph.D.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 23, 1872.

This number contains, in addition to several original papers and memoirs relating to mathematics, natural philosophy, geology, astronomy, and natural history, the following original papers relating to chemistry:—

New Method for Preparing Chromic Acid.—E. Du villier.—The process consists in the decomposition of chromate of baryta by nitric acid. 100 parts of the chromate of baryta, 100 of water, and 140 of nitric acid (sp. gr. = 1.384) are boiled together for ten minutes; it is essential that the water be first added to the chromate, so as to form with it a kind of thickish magma, to which the nitric acid is next added. After ebullition, there are added 200 parts of water, and then the mixture is again boiled for ten minutes; on cooling, the greater part of the nitrate of baryta is deposited in crystalline state, but, after decantation, a further evaporation is required to eliminate the rest of the nitrate of baryta, which, however, may be got rid of by means of dilute nitric acid, thus yielding a solution of chromic acid, which crystallises after evaporation to a small bulk. By this method, very pure chromic acid is obtained, while none is left behind in combination with the baryta.

Different Vibratory Motions Produced by Explosive Compounds.—P. Champion and H. Pellet.—This essay contains the record of a series of experiments made with the view of studying the vibratory motions caused by the explosion of iodide of nitrogen, fulminates, and nitro-glycerine. It appears that, under certain conditions, the vibrations produced cause musical sounds to be distinctly recognised.

Journal de Pharmacie et de Chimie, September, 1872.

This number contains the following original papers and memoirs more particularly relating to chemistry:—

General Method of Immediate Organic Analysis.—Dr. Fleury.—The conclusion of this monograph. This portion is divided into the following sections:—Treatment with cold water; treatment with boiling water; treatment with dilute hydrochloric acid; treatment with caustic potassa; distillation with water; distillation with acidulated water; distillation with an alkali.

Existence of an Organic Alkali in Boldo.—E. Bourgoin and C. Verne.—The boldo is a tree, a native of Chili, belonging to the natural order of the *Momoniaceae*, described by Baillon as *Prunus boldus*; the leaves of this tree have an aromatic camphor-like taste, and contain an essential oil, and an alkaloid which the authors term boldine, which is extracted from the dry and previously-pulverised leaves by first eliminating the essential oil and other complex volatile principles, and next treating the residue with alcohol at 90 per cent containing tartaric acid in solution. By a rather tedious and lengthy process of purifying, the boldine (the leaves operated upon by the authors only contained 1-100th part of that substance) is set free; it is difficultly soluble in water, to which it imparts, however, an alkaline reaction and very bitter taste. Boldine crystallises, is soluble in alcohol, ether, chloroform, and benzene, and, when dissolved in acids,

it is precipitated by ammonia and by the double iodide of mercury and potassium; with iodine-water, this solution yields a chestnut-brown colour; nitric and sulphuric acids impart in the cold a red colour to bolder.

Although not strictly belonging to chemistry, we call attention to the following excellent memoir:—

Report on Absinthe.—MM. Boudet, Dubail, and Adrian.—The authors, having been requested to make a full inquiry into this subject (absinthe being very largely abused in France), have thoroughly investigated the matter, and come to the conclusion that the *liqueurs d'absinthe* are strictly dangerous poisons.

Bayerisches Industrie und Gewerbe-Blatt, September, 1872.

This number contains the following original communications and papers relating to chemistry and collateral matters:—

Rules to be Observed in the Management and Firing of Steam-Boilers so as to Prevent Explosions.—W. Born.—Valuable advice concerning the care to be taken with all that relates to steam-boilers.

Coating of Metals with Nickel by the Aid of Galvanism.—Prof. Böttger.—This lengthy essay treats not only on the electro-nickeling of metals, but also on electro-plating in general.

New Method of Gas-Lighting.—Dr. G. Feichtinger.—This paper, illustrated by a woodcut, contains the detailed account of an ingeniously-contrived and simple arrangement by which benzoline is applied, without a wick, for the production of a cheap and brilliant light, which is already largely applied in many parts of Germany.

Treatment and Removal of Stains of Various Origin from Woven Fabrics.—Dr. L. Rigler.—In a tabulated form, the author gives brief, but useful, hints for the suitable treatment of stains of various nature on dyed, as well as white, woven fabrics of silk, wool, cotton, and flax.

Annales de Chimie et de Physique, October, 1872.

This number contains the following original papers and memoirs:—**Researches on Dulcitol and on Sugars in general.**—Dr. G. Bouchardat.—The conclusion of the monograph on this subject.

Expression of the Elastic Force of a Saturated Vapour in Relation to Temperature.—L. Saint-Loup.—An algebraico-physical essay.

Spontaneous Ascension of Liquids in Capillary Tubes.—C. Decharme.—Illustrated by engravings and several tables exhibiting the results of experiments.

The American Journal of Science and Arts, September, 1872.

In addition to original papers relating to astronomy, natural philosophy, natural history, geology, and palaeontology, this number contains the following paper bearing on chemistry:—

Red Oxide of Zinc of New Jersey.—A. A. Hayes.—This mineral, which has been known for some forty years, has often been the subject of scientific research, on account of its peculiar colour, and the contents of this memoir are mainly devoted to the discussion of the cause of that colour. The composition of the mineral, in 100 parts, is: Oxide of zinc, 93.48; protoxide of manganese, 5.50; scales of specular iron, 0.44; ferric deutoxide, 0.36; loss, 0.22. According to the author, the colour exhibited by this mineral is due to a silicate of zinc, calcium, and ferric oxide, which is dispersed through the mineral in mica-like fashion. Some specimens of the mineral carnallite present a full rich red colour, due to a similar cause, viz., the mica-like dispersion of specular iron scales through it.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, October, 1872.

Applications of Electricity.—Th. du Moncel.—A report by the author on several electrical apparatus constructed and improved by Trouvé. This memoir, illustrated by woodcuts, contains a detailed account of improved galvanic elements, electro-magnetic apparatus for medical use, apparatus for military telegraphy, and apparatus for extracting rifle-balls from wounds.

Report on the Artificial Manure and Works of MM. Dunod and Bouglieux.—J. Barral.—The detailed description of the bone-black and artificial manure works situated at Aubervilliers, near Paris; very perfect and excellently working apparatus are in use for condensing the volatile products derived from the carbonisation of bones.

Relation of the Eye and the Ocular Glasses chiefly in Use in Optical Instruments.—F. P. Leroux.—The concluding portion of this essay, illustrated by woodcuts and engravings.

Metalliferous Mines of France, not including Iron Mines.—A. Caillaux.—The conclusion of this essay.

Pharmaceutische Zeitschrift für Russland, No. 12, 1872.

This number contains the following original papers relating to chemistry:—

Testing of Quinine for Adulterations.—J. Biel.—1 part of sulphate of quinine is dissolved in the smallest possible quantity of dilute sulphuric acid; next, 12 parts of ether and excess of ammonia (2 parts) are added, and this mixture, contained in a test-tube, is well shaken up; a white-coloured turbidity and crystalline precipitate indicate the presence of cinchonine. 1 part of sulphate of quinine is rubbed up in a mortar with 20 parts of a decimal solution, at 15°, of Seignette salt (tartrate of potassa and soda); the fluid is next filtered, and, to 5 parts of the filtrate, 1 part of ammonia (sp. gr. = 0.96) is added; a white turbidity of the previously shaken-up liquid indicates the presence of β -cinchonine. The residue of the former operation is next treated with 20 parts of a solution of sulphate of soda (1 to 3), and, to 5 parts of the filtered solution, 1 part of ammonia is again added; a white turbidity indicates cinchonidine. 5 c.c. of the cold saturated aqueous solution of pure sulphate of quinine require 4 c.c. of ammonia (sp. gr. = 0.92) to yield a clear solution. 5 c.c. of the aqueous solution of pure sulphate of quinine and 10 per cent of β -sulphate of cinchonine gave, with 5 c.c. of ammonia, a strong turbidity, which was got rid of by the addition of 4 c.c. more of ammonia; but, after two minutes, a crystalline precipitate appeared, which required the further addition of 10 c.c. to render the liquid clear. Pure sulphate of quinine, mixed with 10 per cent of cinchonidine sulphate, 5 c.c. of solution, and 5 c.c. of ammonia, yielded an opalescent fluid, which was rendered quite clear by the addition of 3 c.c. of ammonia, but, after five minutes, the precipitate was stronger than before. 5 c.c. of the solution (aqueous) of pure sulphate of quinine and 10 per cent of sulphate of cinchonine yielded, upon the addition of 5 c.c. of ammonia, a strong precipitate, which was hardly dissolved by the addition of 200 c.c. of ammonia.

Detection of Caffeine in Tea-Leaves.—E. Lieventhal.—The description of a rather complicated process of extracting caffeine from tea-leaves by exhaustion of the same with chloroform.

Nos. 13 and 14, 1872.

These numbers only contain original papers relating to pharmacy and pharmacognosy.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, June 24, 1872.

New Mode of Treatment of Scraps of Tin-Plate for the Purpose of Obtaining the Tin Coating from it.—M. Ott.—This paper contains a brief *résumé* of the several methods proposed to recover the metallic tin coating which covers the material known as tin-plate, and a detailed description is given of a process invented by the author; it consists mainly in the methodical treatment of the scraps of tin-plate, first with acid, then with water, then with alkali, and again with acid; the tin is precipitated from its solution by means of metallic zinc, and the spongy metal thus obtained is next molten.

Frigerific Apparatus.—Ch. Tellier.—The description, illustrated by a woodcut, of a peculiarly constructed ice-safe, so arranged as to be a neat piece of useful furniture.

Preparation of Chlorine by a Continuous Process.—Tessié du Motay.—This process is based upon the following reactions:—Peroxide of manganese is first gently heated in a retort, in contact with hydrochloric acid gas; chlorine is evolved, while there is left in the retort chloride of manganese and water—

The chloride of manganese thus obtained is next heated to dull red heat in a fire-clay retort, and decomposed by means of a current of steam into hydrochloric acid and sesquioxide of manganese, but if, along with the steam, there is mixed a sufficient quantity of air or oxygen, there is produced a mixture of chlorine and hydrochloric acid, while peroxide of manganese is regenerated. The hydrochloric acid last mentioned may be converted into chlorine by simply causing air (without any steam at all) to pass at dull red heat over the chloride of manganese— $\text{MnCl} + \text{O}_2 = \text{MnO}_2 + \text{Cl}$.

New Process for Bleaching Woollen and Silk Fabrics.—Samal and Beronson.—In order to wash the suint from wool, and the gum from raw silk, the authors apply a more or less concentrated and more or less warm (up to 50°) solution of an alkaline sulphuret or aluminate.

Les Mondes, September 19 and 26, 1872.

These numbers contain no original papers relating to chemistry or collateral subjects.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, May, 1872.

This number contains no original papers relating to chemistry or collateral subjects.

Journal für Gasbeleuchtung und Wasserversorgung, No. 15, 1872.

This number contains no original papers relating to chemistry, but we call attention to the following memoir:—

Report on the Results of the Competition for Water-Meters, as required by a Programme issued by the Directors of the City of Hamburg Water-Works.—J. A. Samuelson, C.E.—This paper contains valuable information concerning water-meters.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents,
54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2596. J. Hargreaves and T. Robinson, Widnes, Lancashire, "Improvements in the manufacture of salt."—Petition recorded August 31, 1872.
2610. J. Noad, Hackney Wick, Middlesex, "Improvements in the manufacture of paper pulp from wood, and in apparatus therefor."—Petition recorded September 2, 1872.
2642. C. W. Torr, Aston, near Birmingham, and J. Johnstone, Birmingham, "Improvements in furnaces for heating and melting metals and metallic alloys."
2644. J. Harvey, Vere, Jamaica, "Improvements in the manufacture of sugar, and in apparatus therefor."—Petitions recorded September 5, 1872.

NOTICES TO PROCEED.

1476. R. C. Menzies, Valleyfield, Midlothian, N.B., and A. E. Davies, Worcester, "Improvements in the manufacture of pulp for paper-making."—Petition recorded May 15, 1872.
2429. T. J. Denne and A. Hentschel, Mile End, Middlesex, "Improved combination of ingredients for treating, preparing, stiffening, and thickening raw, felted, spun, and woven fibres and fabrics, also for use in dyeing and printing such fabrics and fibres."—Petition recorded August 15, 1872.
2454. W. Ferrie, Airdrie, Lanarkshire, N.B., "Improvements in connection with furnaces for smelting iron."—Petition recorded August 17, 1872.

PATENTS SEALED.

835. N. Prada, Trebbin, near Berlin, Prussia, "Improvements in preserving animal substances, and in agents for the purpose."—Partly a communication from P. Toninetti, Trebbin.—Dated March 19, 1872.
865. J. Werner, Mannheim, Baden, Germany, "An improved composition to be used as a substitute for brewer's pitch for lining vats, casks, and tubs, and for other like purposes."—Dated March 21, 1872.
880. H. Hollefreund, Havelberg, Prussia, "Improvements in the treatment of potatoes, maize, corn, millet, and other starch-containing vegetable matters, to obtain saccharine and other products therefrom, and in apparatus employed therein."—Dated March 22, 1872.
908. G. J. Snelus, Dowlais, Glamorganshire, "An improved lining for cupola furnaces, also applicable to the formation of the beds of reverberatory furnaces."—Dated March 25, 1872.
943. A. Beveridge, Leith, N.B., "Improvements in preparing, cleansing, and refining animal fats, and in the means and apparatus employed therefor."—A communication from A. Jurgens, Oss, North Brabant, Holland.—Dated March 30, 1872.
1386. W. R. Lake, Southampton Buildings, London, "Improved processes and apparatus for the extraction of oil and the production of flour from maize."—A communication from H. C. Cayavé, Paris.—Dated May 24, 1872.
2261. W. E. Gill, Salisbury Street, Strand, "Improvements in treating vegetable juices, and in the apparatus and materials to be employed therefor."
2263. G. T. Bousfield, Sutton, Surrey, "Improvements in furnaces for deoxidising iron ores, preparatory to their being worked into wrought iron."—A communication from J. Wilson, Dover, New Jersey, U.S.A.—Dated July 29, 1872.

PATENTS GRANTED IN BRITISH COLONIES.

MAURITIUS.

LIST OF PATENTS GRANTED FROM 1838 TO 1872, BOTH INCLUSIVE.

1. J. B. Hélie, "Purifying sugar."—Dated November 14, 1838.
2. F. L. W. Terrasson and C. Lieber, "Purifying and filtering cane-juce in the manufacture of sugar."—Dated August 24, 1840.
9. H. A. Hugnin, "Purifying sugar."—Dated February 15, 1845.
12. F. Bernard, "Purifying sugar."—Dated September 4, 1847.
14. W. Bojer, "Manure from night-soil."—Dated November 22, 1849.
18. V. N. Monneron, "Guano, manufactured from sea animals, plants, and other ingredients of this island."—Dated February 18, 1853.
19. J. Brandees, "A new process for the manufacture and purifying of sugar, &c."—Dated April 23, 1853.
20. E. Deschamps, "Wine from sugar-cane."—Dated May 27, 1854.
21. L. Wray, "A new process for employing the plant called *Holcus saccharatus* in the manufacture of syrup, molasses, sugar, vinegar, &c., and also for the treatment of the cold raw juice of the said *Holcus saccharatus*, or of any other cold raw saccharine juice, with lime and other suitable substances, and then the filtration of the said juices."—Dated February 7, 1855.
24. G. Garbert, "Disinfecting pulverised charcoal."—Dated March 14, 1856.
25. A. Raynaud, "Spirits of wine distilled from rum and brandy."—Dated August 27, 1856.
26. C. Lieber, "A new process for manufacturing rum."—Dated March 9, 1857.

34. A. P. D'Esmer, "Artificial manure for agricultural purposes more particularly adapted for the cultivation of sugar-cane."—Dated March 25, 1859.
35. A. P. D'Esmer, "A composition to be used as a disinfectant and for the cure of sores."—Dated November 26, 1859.
36. Dr. H. F. Fresanges, "A composition to be used as a disinfecting and deodorising agent."—Dated December 6, 1859.
40. P. Boileve, "A new method of defecating sugar and other saccharine matters and of refining or rectifying alcohol."—Dated June 9, 1860.
47. F. Martial, "Vermicelli and macaroni."—Dated July 2, 1861.
50. H. I. V. Portal, "A process for purifying the juice of the sugar-cane, and which process consists in a special mode of employing lime for the purpose, and in also employing some carbonate or neutral sulphite."—Dated November 13, 1861.

VOL. XXVI. No. 672.

THE AMMONIA PROCESS OF WATER ANALYSIS IN INDIA.

By EDWARD NICHOLSON, F.C.S., Assist.-Surg. R.A.

I OWE some amends to Messrs. Wanklyn and Chapman for having, some months ago, hastily depreciated their ammonia method of estimating organic matter in water. The best amends I can make is to give an account of the results obtained by the process, both in my own experience and in the published results of other analysts' work. The first specimen of official results I saw were rather wild; whether *grms.* had been misprinted for *milligrms.* I know not, but "albumenoid ammonia 0·1750 grm. per litre" in a good spring-water looks peculiar. There is no appearance of misprint about it, and I attributed the extraordinary amount to the eccentricity of the condensing arrangements in the government apparatus.

I since have had access to the Reports of the Bengal water analyses, and find that in 1869 Dr. Macnamara, Chemical Examiner to Government, and in 1869-70 Dr. Palmer, his substitute, made ammonia examinations of the waters of Calcutta and the neighbourhood; I am thus enabled to compare the results obtained by two successive analysts on the same waters.

I have been able to trace examinations of three or four waters for several successive seasons; peculiarly enough, each examination appears to yield more and more ammonia, though the organic matter by the permanganate does not increase notably.

Centigrms. per litre.			
	NH ₃ .	Alb. NH ₃ .	Oxygen of Permanganate.
Old tank on the glacis of Fort William, supplied by surface drainage*:-

		0·012	0·06

There are considerable discrepancies in the above results; for instance, the new tank water, requiring 0·09 centigram. of permanganate oxygen, and containing 0·056 centigram. of albumenoid ammonia, is filled up from a comparatively pure river; the permanganate oxygen increased to 0·31 centigram., and the albumenoid ammonia decreases somewhat. If, as is likely, the disturbance of the water caused an increase of oxygen to be consumed by oxidisable matter, the albumenoid ammonia should have increased also. With the subsidence of the water,

* The water of the above tanks is, after filtration, the drinking-water of the European troops in garrison.

the quantity of permanganate used fell rapidly to the original amount, while the albumenoid ammonia still increased. I can understand, in this case, the results of the permanganate much better than those of the ammonia process.

The increased amount of permanganate required led the Chemical Examiner into a curious error; he says, "fresh water had been pumped in from source which, though less impure in most respects (albumenoid ammonia) contained a loathsome amount of impurity." A few weeks afterwards he finds that the tank was re-filled from the river Hoogly, and examines the river-water with the results given above. I strongly suspect these albumenoid ammonia figures are much less trustworthy than those of the permanganate.

Within the last few days I have received the "Report of the Madras Water Examinations" for the year 1871. One of the analysts, Mr. Harvey, has been for some years assistant to the successive Professors of Chemistry in the Madras Medical College; I know that his work can be relied on as conscientious, and his results will therefore afford a fair criterion. From his connection with the chemical department of the Medical College, he would have access to corks, india-rubber tubing, and such like necessities for fitting up apparatus, enabling him to work the ammonia process without difficulty.

The details I unfortunately cannot give, owing to the muddle which the compiler or the printer has made of the analyst's figures, 0·06, 0·006, 0·0006, and 0·00006 grm. being evidently interchangeable; the whole report, as far as figures go, is full of mistakes. Mr. Harvey says, of the waters of St. Thomas's Mount:-

"By the permanganate, as well as by the ammonia process, the quantity of organic matter found is remarkably small; and, assuming the albumenoid ammonia obtained to express the purity, or otherwise, of drinking waters, with one exception, none of these waters exceed the standard laid down by Messrs. Wanklyn and Chapman for a pure water, the albumenoid ammonia obtained ranging from 0·03 to 0·08 per million. They may, therefore, be regarded as waters of very great purity, and unquestionably well adapted for drinking and other domestic purposes." However, seven out of twelve of these well-waters are too brackish to be potable.

The Palaveram waters examined by the same analyst were much of the same character. The best well (containing 20 centigrms. of total solids, 2 of which were chlorine, requiring 0·04 centigram. of permanganate oxygen, and yielding 0·05 centigram. of albumenoid ammonia) was in a locality used as a rubbish and sweepings depot; it was only 18 feet deep. This shows the little effect of surface pollution on sub-soil water.

The analyst at Rangoon gives figures for the results of the ammonia process, but they are of such a peculiar character that I hardly like to quote them; numbers such as 0·0032 grm. of ammonia and 0·0006 grm. of albumenoid ammonia are common. A good well-water requiring 0·0010 grm. of oxygen is said to yield 0·00470 grm. of ammonia and 0·0040 grm. of albumenoid ammonia.

Three examinations of water from the Rangoon lake, a beautiful piece of clear and pure water with which I am well acquainted, are said to have given the following results:-

	Grm. per litre.		
	(a.)	(b.)	(c.)
Ammonia	0·006	0·012	0·008
Albumenoid ammonia..	0·016	0·014	0·016
Permanganate oxygen	0·010	0·011	0·0107

I cannot consider the determination made by the ammonia process at Rangoon as being in any way trustworthy.

The analyst at Secunderabad did not give any results of the ammonia process; and, considering that the apparatus supplied to the analysts consisted of a retort and a clumsy copper condenser that would not condense (without the slightest means of connecting the two), he acted wisely.

For my own part, I made no systematic ammonia examinations until I had got out apparatus of my own; at the end of the year I began the process, and have obtained the following results from various waters:—

WELLS.	Centigrams, per litre.		
	Ammonia.	Alb. Ammonia.	Oxygen of Permanganate.
The Dhobies wells, Bangalore; water 6 feet from the ground, percolated from the Ulsor tank through a gravel bed; 16 wells all communicating:—			
(1). A well not in use, ground clean . . .	0'0005	0'005	0'015
(2). A well in use, ground trampled into mud by the bullocks carrying water to the troops; water drawn by leathern buckets	0'0020	0'008	0'020
(3). A well on the ground now used by washermen; clothes constantly washed close to the well	0'0020	0'026	0'040
A well in Bangalore gaol, conservancy perfect	0'0010	0'006	0'010
A well, very open, water kept low by constant draught; supplies Artillery horse-troughs	0'0060	0'010	0'240
Water from the above well, filtered at barracks; filter receptacle open and not looked after	0'0030	0'026	0'230
A well, large and open, used solely for supplying barracks, by means of an aqueduct; ground perfectly open, irreproachable, and the well guarded; the water is always yellow, from humic organic matters; of excellent quality	0'0030	0'021	0'300
A large open well, with steps; people constantly going down to fill their water-pots, wading for a little distance in the water; water covered with <i>Conferva crispa</i> ; in great demand	0'0060	0'020	0'060
A well in great use, very muddy all round from trampling of bullocks; ground open, conservancy otherwise good	0'0030	0'024	0'030
TANKS.			
Water supplied to troops from the water-works at Ulsor tank; the water, before filtration, is opaque with yellow clay; after filtration (through 5 feet of sand) it is clear and good; the conservancy of the tank is very good, but the vegetation is entirely confervaceous	0'0020	0'014	0'080
A tank without vegetation, except <i>Conferva</i> ; greenish coloured water, with much water fleas; water in great demand	0'0070	0'022	0'140
A small tank, in which people are all day wading to fill their water-pots; water turbid and swarming with water-fleas; no vegetation; conservancy good	0'0100	0'043 (1st., 0'046) (2nd., 0'041)	0'080

It is not easy, in the present state of our knowledge, to draw conclusions as to the standards of purity exigible from Indian waters, or as to the interpretation we should give to the figures representing organic impurity. As far as I can see, good waters vary exceedingly; the following standards appear to be approximately applicable:—

WELL WATERS.	Alb. Ammonia.	Permanganate NH ₃ .	Oxygen.
Standard; good filtering soil; water clear and colourless, not much disturbed in drawing	0'007		0'02
The same, but much disturbed; ground muddy	0'015		0'04
Open reservoir-wells, with vegetation, disturbed by peoples feet, &c.	0'020		0'10
TANK WATERS.			
Standard; not much vegetation; well filtered from animalculæ and suspended matters . .	0'015		0'10
Much vegetation	0'020		0'30
Little vegetation; much animalculæ	0'025		0'10

Quantities above the standards should lead the analyst to examine how far they may be due to pollution by putrescent or organic matters. No water should be condemned without being judged on the full evidence derived from—

(a). Mineral matters compared with those of good waters in the same drainage-basin.

(b). Organic matters estimated by ammonia process and the permanganate test.

(c). Examination of physical properties.

(d). Full inquiry into the condition, past and present, of the drainage-ground.

The seventh well in the above list is an example of a water that would be condemned if the evidence of the organic matter were alone taken. Thorough examination showed that the organic matter must be of humic origin; the water is perfectly wholesome and pleasant.

On the whole, I may say that the ammonia process gives a fairly accurate estimate of the amount of nitrogenised organic matter in the water, but other evidence must be adduced in order to show the origin of the nitrogenised substances. I find that there is a good deal of difficulty in getting rid of the free ammonia, and am disposed to think that much of it properly belongs to the albumenoid ammonia. With regard to the applicability of the process to Indian sanitary requirements, I think that India is too far backwards yet for it, and that it is too delicate to be trusted in the hands of analysts and others who have received no chemical education.

ON A PROBABLE CHEMICAL AND INORGANIC ORIGIN OF THE ATLANTIC OOZE AND THE CHALK.

By THOMAS P. BLUNT, M.A., F.C.S.

A VERY probable and ingenious answer has lately been suggested to the question, "Why is the sea water salt?"—an answer which carries conviction with it, because it shows, by a prior reasoning, that the sea must necessarily contain large quantities of chloride of sodium, or at least of soluble chlorides. The process of reasoning may be stated as follows:—

A constant distillation of pure water is taking place from the enormous surface of the ocean by the solar heat; clouds are formed, which drift in part over the continents, and on coming into contact with the necessary climatic conditions fall as rain; this in its turn filters drop by drop through the soil and forms the springs which overflow and produce the rivers and streams. The water of the latter, however, is no longer pure, but is found on analysis to contain on an average about 0.7 grain of chlorine per gallon,* derived no doubt from the soil, and probably in most cases in combination with sodium. The water thus charged with chlorides reaches the sea, where it is subjected to the concentrating process described above, and so time after time the soil is lixiviated, the chlorides dissolved out of it accumulating in the ocean.

The above theory only requires to be stated to commend itself at once as the most probable and natural explanation of the saltiness of the sea, however the latter may be augmented in certain regions by the discharge of brine-springs. But it must be remembered that chlorides are not the only solid contents of spring and river water: for every grain of chlorine present in them, we find on an average from 6 to 8 grains of carbonate of lime; what, then, is the destination of this latter constituent? Clearly, as soon as the carbonic acid, which alone renders it soluble, is dissipated by the sun's heat at the surface of the sea, it will subside in fine particles to the bottom, there forming a "fur" similar to, but less consistent, than the deposit which causes constant annoyance in our steam boilers, and even in the domestic tea-kettle similar to the latter, for its origin and chemical character are the same, but differing in consistence on account of the far more gradual and gentle manner in which it is separated,

* It should be mentioned that *natural* water is here referred to, the writer found 0.8 grain of chlorine in the water of a spring situated in a remote part of the Welsh hills.

which causes it to appear as the fine mud or "ooze" described as coating the lower half of the recovered Atlantic cable.

It is not, of course, denied that the sediment thus produced is largely supplemented by the chalky exuvium of marine animal life, or that the deposit may not in parts even mainly consist of the latter, but it is maintained that the greater portion of the amorphous "ooze," and of the chalk, which appears now to be identified with it, must necessarily be the product of a purely chemical process of the kind described; otherwise we are at a loss to account for the disposal of the enormous weights of carbonate of lime carried daily into the sea by the rivers.

ON A

NEW PROCESS FOR THE ESTIMATION OF IODINE IN KELP LIQUORS, MINERAL WATERS, &c.

By E. SONSTADT.

THE addition of an alkaline permanganate to a liquid containing an iodide in solution, converts the iodide into an iodate, provided sufficient free alkali, or alkaline carbonate is present to prevent liberation of iodine. This fact (which I discovered early in the present year, in the course of investigations having for their object the effecting of improvements in the manufacture of iodate of potassium direct from the mother-liquors of kelp, instead of from iodine, as hitherto practised), I have found very serviceable for the estimation of iodine.

Alkaline solutions of chlorides and bromides are not in the least acted upon by permanganate solution. But neither chlorides, bromides, nor any other salts that ordinarily occur with iodides, interfere with the transformation of iodide into iodate by permanganate. Even organic matter does not interfere, provided the permanganate is added in sufficient excess. The process I adopt consists simply in adding excess of permanganate of potassium to the solution of salts containing iodide, until a slight permanent tint of permanganate colouration remains. The solution is first rendered alkaline, best by addition of caustic soda, to an extent adjusted to the proportion of iodide present; but always so far as to preclude any possibility of the liberation of iodine. The liquid is then filtered, and if it does not already contain a sulphate, a small proportion of a sulphate is added to it. Solution of chloride of barium in excess—but not in much excess—is then added, and the precipitate, after separation from the liquid by filtration and washing, is heated with solution of sulphate of potassium in excess. The filtered solution contains the whole of the iodine originally present in the portion taken for analysis, as iodate of potassium. The quantity of iodic acid may be estimated volumetrically by any of the usual processes; or the mixture of iodate and sulphate may be ignited at a low red heat, and the iodide of potassium remaining be estimated either volumetrically or gravimetrically.

In this process, the transformation of iodide into iodate by permanganate in alkaline solution is *complete*. The precipitation of the iodic acid by a barium salt in presence of a sulphate is *complete*. The decomposition of iodate of barium by heating with solution of sulphate of potassium in excess, is *complete*. By the word "complete," I mean within appreciable limits. That is to say, I have, in the course of many experiments specially devoted to that end, been unable with certainty to detect even a trace of iodine either in a liquid in which an iodide had been transformed into iodate as described, and precipitated, in presence of a sulphate, by chloride of barium; or in the barium precipitate, after heating with sulphate of potassium in excess, filtering, and duly washing.

The severest test that can be applied to a process of this kind, is not to use it upon weighed quantities of an iodide, but to try it upon liquids containing, for the quantity taken, imponderable quantities of an iodide or of an iodate. The experiments that have already been described on sea-water, in my paper "On the Presence of Iodate of Calcium in Sea-water," afford a good illustration. In these experiments, one part of iodate of calcium in a quarter million parts of liquid, sufficed, in such a quantity of the liquid as did not contain a ponderable quantity of iodine, to give measurable iodine reactions in the precipitate thrown down by chloride of barium. And yet, if we suppose the whole of the iodine in sea-water to exist as iodate of barium, after addition of a barium salt, the sea-water would contain only about 1 per cent of a saturated solution of that salt. I at first supposed this very complete precipitation of iodic acid by barium salt in sea-water to be owing to some element contained in my chloride of barium, that formed an iodate much less soluble than any that had been described. I therefore took a considerable quantity of the same chloride of barium that had been used in these experiments, and precipitated it fractionally by solution of pure iodate of potassium at three times. All the precipitates had sensibly the same degree of solubility in water. Iodate of barium is remarkable, however, in this; that it dissolves with such extreme slowness in even boiling water, that it is the work of days with the aid of heat, to get a really saturated solution. The water used in these experiments had been carefully distilled off permanganate of potassium, since water not perfectly free from organic matter cannot be trusted for solubility determinations of the iodates. The results I obtained agreed nearly enough with the published determinations of the solubility of iodate of barium to convince me that the complete precipitation of iodic acid in presence of sulphuric acid by a barium salt, is due to surface attraction, between sulphate of barium formed in the liquid, and nascent iodate of barium. If we consider how many square metres of surface a single gramme of so finely divided a precipitate as sulphate of barium usually is must present, the property that this salt is supposed to enjoy above all others, of carrying down with it other more soluble salts, ceases to appear inexplicable. Yet this power certainly is not exercised solely in obedience to the degree of solubility of the salt so pulled, by mechanical attraction, as it were, out of solution. A *colloid* salt and a *crystalloid* salt seem to have no pulling power upon one another; and crystalline salts apparently are subject to such influence under some law connected with the complexity of their crystalline form. Again, two colloid salts, as the hydrates of alumina and of ferric oxide, scarcely admit of complete separation.

FLUORESCENCE.

IN a series of papers to *Poggendorff's Annalen*, Herr Hagenbach describes extensive researches on this subject. We propose here to give a brief statement of his results.

To the question whether all the rays of the spectrum are capable of exciting fluorescence, he considers an affirmative answer may be given. As to excepting the red rays before B, from which fluorescence was not obtained, it is to be considered, that since fluorescent light is always less refrangible than the exciting light, fluorescence excited by the extreme red may not be visible by our eyes.

As to the extent of fluorescence in the spectrum, there are cases (as that of fluor-spar), in which it only begins in the violet after G; and others (as chlorophyll) in which it is spread over the entire spectrum. No fluorescent substance was met with which did not fluoresce in the neighbourhood of the line H.

The maxima of the fluorescence were very various.

From 7 maxima, e.g. in chlorophyll solution, to 1 maximum (so to call it) in ether and sulphuric acid. In some cases the difference between maxima and minima was very perceptible, in others not.

Stokes's law, that where rays excite fluorescence a corresponding absorption takes place, was verified. The absorption spectrum could thus frequently serve to determine more accurately the maxima of fluorescence. But it is frequently found that absorption of light occurs without corresponding fluorescence. Herr Hagenbach observed, e.g., in a water solution of litmus an absorption additional to that corresponding to the fluorescence. This is probably explained, he thinks, by the mixture of a fluorescent with a non-fluorescent substance.

As to the spectrum of fluorescent light, there is also great variety in this. The spectrum with least extent was that of chlorophyll; while those of fluor-spar and miomelanin acid were among the most extended. With regard to "intermittence" in the light intensity, we have various cases. From 8 maxima in nitrate of urea, 6 in bichloride of anthracene and petroleum, down to 1 maximum, and so no intermittence, in naphthalene, red nitrate of chrysianilin, and others. The difference of brightness between maxima and minima is, as in the former case, well marked in some substances, and in others not.

Is there any correspondence between the intermittence in the fluorescence of the spectrum (the fluorescent spectrum) and that in the fluorescence spectrum? In some cases there appeared to be such, as e.g. in extract of soot, which gave 5 maxima in both spectra. But other cases showed there is no necessary connexion between the two. Thus the solution of fresh chlorophyll gave 7 maxima in one spectrum and only 2 in the other. Naphthalene showed 3 maxima in one spectrum, and no intermittence at all in the other. Nitrate of uran, giving 8 maxima in the fluorescence spectrum, gave no intermittence in the ordinary spectrum.

Is the intermittence of fluorescence in the one case or the other to be explained by mixture of fluorescent substances? This is Von Pierre's hypothesis. While it is possible to produce intermittence artificially through mixture, Herr Hagenbach considers that in many instances the hypothesis is improbable. Then in the case of a fresh solution of chlorophyll giving intermittence (which, it is said, arises from the mixture of various different materials), it would at least be a singular thing that in all kinds of plants containing chlorophyll, the materials were mixed in like proportions, and that all the materials which by the different rays were excited to fluorescence should give the same fluorescence spectrum.

Stokes's law that in fluorescence light the rays called forth are never more refrangible than the exciting rays, was found in every instance to hold good.

Herr Hagenbach also verified Von Pierre's propositions as to the connexion between the exciting and the excited rays.

With reference to the influence of the solvent on the character of the fluorescence, it was found, in many cases, that do change in effect arose from changing the solvent; in other cases, the maxima of the fluorescence or of the fluorescence spectrum, were displaced. Several instances are given. Thus in ether solution of amide of phthalic acid, the beginning and maximum of fluorescence are nearer the violet end than in the alcohol solution. The same thing is found in similar solutions of chlorophyll.

Kraus made the observation, that the thicker a solution is, the further are absorption-bands moved towards the red end of the spectrum. As fluorescence maxima and absorption-bands correspond, Herr Hagenbach considers his experiments may serve to confirm Kraus's view; but that the data as to the relation between fluorescence and absorption are as yet somewhat insufficient. Cases of displacement (through change of solvent) in the fluorescence spectrum are further given; and the author asks

whether a displacement of the maxima of fluorescence is always accompanied by a displacement in the fluorescence spectrum. In the ether and alcohol solutions of amide of phthalic acid, the ether and alum solutions of purpurin, and other instances, this was found to take place; but in others, as a solution of extract of soot with oil of turpentine, compared with a solution of the same substance in ether or alcohol, it did not.

The question whether fluorescence in the solid state implies fluorescence in a state of solution, and *vice versa*, must be answered differently for different substances.

Some substances fluoresce in the solid state, and not at all in solution; some greatly in the one state, little in the other; some show strong fluorescence in both states; some fluoresce little in the solid state, and greatly in solution; some fluoresce only in solution.

Herr Hagenbach considers it probable that phosphorescence and fluorescence are phenomena differing in degree only, not in kind; though further data are necessary to the elucidation of this. He finds much similarity between the fluorescence spectra and many of the spectra of phosphorescent substances.

A. B. M.

ON THE CONCENTRATION OF SULPHURIC ACID.

By R. HASENCLEVER.

It is well known that the sulphuric acid prepared in the leaden chambers is first concentrated up to a sp. gr. of 2.7 in leaden apparatus; while the further concentration to 66° Baumé (sp. gr. 1.85) is carried on in vessels made of glass or platinum. All the leaden apparatus used for the purpose of concentrating the chamber acid to 60° Baumé (sp. gr. 1.7), are more or less acted upon by the acid; and it is of great importance to be well acquainted with the behaviour of the lead with acid at different temperatures. Experiments made in the chemical laboratory of the Chemical Works, Rhenania, proved that when pure sulphuric acid was evaporated in a vessel made of doubly refined lead, sulphurous acid was given off at a temperature of 165° to 178°, and at a degree of concentration of the acid at 57° Baumé (1.659 sp. gr.), there was a distinct smell of sulphuretted hydrogen. While at 80°, and with an acid at 58° Baumé (1.678 sp. gr.), a very strong decomposition of the acid, attended by violent foaming and deposition of sulphur, commenced. The same phenomena have been observed on the large scale; by the overheating of the sulphuric acid so much gas was suddenly evolved that the liquid contained in the leaden pan boiled violently, while sulphurous and hydrosulphuric acid, as well as sulphur, were set free simultaneously. Sulphuret of arsenic was formed in acid contaminated with arsenic.

It has often been thought that these phenomena were due to impurity of the lead, and that metal was frequently analysed by the sulphuric acid makers, as well as by lead merchants, who were blamed for the corrosion of the leaden pans; but it appears that only trifling impurities were detected in the lead. At the chemical works above named it became customary to use a thermometer, and by that means the corrosion of the leaden pans due to overheating of the acid was prevented. Some few weeks ago, however, a brisk evolution of gas was observed in one of the leaden pans, while the acid contained therein was only at a temperature of 135°. The gas evolved was found to be hydrogen, while the lead of which the pan was made was moderately pure. Since it was known to me that the complaints of the rapid corrosion of the leaden pans have increased since the lead is de-silvered with zinc, it occurred to me that a pure soft lead obtained according to the new method, would be more apt to become corroded. I procured a sample of Mechernich lead (a locality in

Prussia where lead ore is largely smelted), the composition of which was per centically—Lead, 99.9941; silver, 0.0006; copper, 0.0008; antimony, 0.004; iron, 0.0005. This lead was put into a flask, and pure sulphuric acid of 54° Baumé (sp. gr. 1.601) poured over it. On being heated to 40°, small gas bubbles were seen to be emitted from the lead, and at 80° a distinct and continuous, though not a brisk, evolution of gas took place, which increased with an increase of temperature. The gases evolved were hydrogen and sulphuretted hydrogen. A portion of this same sample of lead was molten and mixed with some antimony, and after cooling, the sample was again submitted to the same treatment with pure sulphuric acid at 54° Baumé. A very faint evolution of gas commenced when the acid was heated up to 85°, and even at 100° this evolution of gas was hardly stronger, but at 140° the evolution of the gases became rather more brisk.

From the results of a series of experiments I am inclined to believe that pure and soft lead does not resist the action of hot sulphuric acid so well as the harder kinds of lead; a fact which is of practical bearing and deserves to be further studied by experiments. As regards the apparatus more commonly in use for concentrating sulphuric acid (chamber acid) these are—

- (1). Evaporating pans made of sheet-lead placed on plates of cast-iron, below which the fire is kindled (direct heating).
- (2). Leaden pans heated by means of a reverberatory furnace (the flame playing over the surface of the acid), the edges of the leaden pans being hollow and filled with cold water in order to prevent the melting of the lead.
- (3). Concentration by means of high-pressure steam.
- (4). Concentration by means of heated sulphurous acid gas.

As regards the first mentioned apparatus, it is absolutely necessary to control the evaporation by means of a thermometer in order to prevent the overheating of the acid, and consequently the corrosion of the lead. When the workman in charge of the operation of evaporating takes due care, and makes frequent use of the thermometer, these leaden pans may last a long time, although they will require frequent repairs, and are not to be recommended for economy in the consumption of fuel and loss of acid. The reverberatory furnace for evaporating acid is an English invention, and has been introduced into Germany some few years since at Lüneburg. These furnaces do not consume much fuel, require little repair, but their use is attended with the inconvenience that the acid becomes readily overheated; while with the smoke and other products of the combustion, much sulphuric acid is carried off. On this account the use of this apparatus has been discontinued in many works. The first suggestion of the application of indirect high-pressure steam to concentrate sulphuric acid (chamber acid) has been made by Carlier, the technical manager of the Chemical Works of F. Curtius, at Duisburg (Rhenish-Prussia). After a series of preliminary trials, the chamber acid, at the works just mentioned, is now evaporated in the following manner:—The acid is poured into a wooden lead-lined tank 4 metres in length and width. On the bottom of this tank are placed two coils of leaden pipes 45 metres long, 0.03 metre internal diameter, and 0.007 metre thickness of lead. Through these coils high pressure steam is forced as long as the tank is filled with acid. In order to cause the water of condensation in the tubes to run off freely, the bottom of the tank is made in the shape of a cut-down pyramid: the depth of the tank in the centre being 0.60 metre, and at the sides 0.30 metre. The ends of the tubes (outlet and inlet) communicate with a steam boiler placed at a lower level than the tank, stopcocks being fitted to the inlet and outlet of the leaden pipes (coil). The inlet of the coil communicates with the steam-boiler below the water-level therein; while the outlet of the coil communicates

with the steam-chest, thus affording an opportunity for the condensed water to flow back into the boiler.

The operation of concentrating the chamber acid is intermittent. The tank having been filled with acid at 1.5 sp. gr., the circulation of steam is kept up until the sp. gr. of the acid has increased to 1.7; this point having been reached, the hot acid is transferred to a wooden lead-lined tank, at the bottom of which is placed a serpentine coil of leaden pipes through which the chamber acid is made to pass before flowing into the concentration tank, so that the latter is filled with acid which is already warm.

In an apparatus of the size and dimensions alluded to, 5 tons of chamber acid are concentrated to 1.7 sp. gr. in 24 hours. The steam in the boiler is at a pressure of 3 atmospheres (= 45 lbs. to the square inch = 135.1° temperature); the quantity of fuel consumed amounts to 9 per cent of the acid concentrated. As regards the feeding of the boiler, this need only be intermittently done by the aid of a force-pump (donkey engine with pump), because the regular supply of water is derived from the condensed steam. It is advisable to construct at a short distance from the top of the tank a wooden hood, so that in the event of any part of the leaden coil placed at the bottom of the concentration tank bursting, the hot acid while being thrown about does no injury.

This method of concentrating chamber acid is in every respect superior to the other plans. The lower temperature prevents volatilisation of acid, which is also not contaminated with soot, dust of ash, and smoke, while the expense is, lastly, considerably less. In many parts of Germany this method of concentrating chamber acid has been introduced.

The hot gases of the pyrites burners are often applied for the purpose of concentrating chamber acid. Sometimes leaden pans are placed on the top of the kilns; or, again, the hot sulphurous acid gas is conveyed into a leaden tower lined with bricks. As regards the placing of leaden pans on the top of the pyrites kilns, this plan is attended with inconvenience, for if the pans become leaky, the whole process of sulphuric acid making has to be suspended, while the acid finding its way into the pyrites burners destroys them. It is therefore better to place the concentration pan on a channel situated between the sulphuric acid chambers and the kilns; so that the manufacture of acid is not discontinued when repairs to the leaden pans are required.

A more perfect and greatly improved application of the hot sulphurous acid gas issuing from the pyrites kilns is made in the so-called Glover's towers, a contrivance frequently employed in England, and fully described in the second number of *Dingler's Polytechnisches Journal* for August, 1871, by Lunge. By the direct action of the heated kiln gases upon the sulphuric acid, evaporation ensues; the sulphurous acid gas is strongly cooled down before it enters the leaden chambers; the sulphuric acid and steam which are volatilised also enter the chambers, so that no loss of acid ensues; while, at the same time, the steam supply to the leaden chambers can be diminished. The sulphuric acid obtained by this method of concentrating chamber acid is not quite free from sulphurous acid, a point to be taken into consideration for certain applications of the acid, in which I found 0.7 grm. of SO₂ to the litre. It should be further mentioned that, when the Glover system is applied, there cannot be simultaneously applied a contrivance to arrest the dust and small particles of partly burnt pyrites carried off along with the sulphurous acid, because by the application of such contrivance the sulphurous acid gas would be too much cooled down to be fit for evaporating purposes, and as a consequence the dust would contaminate the acid, rendering it ferruginous. For the purposes, however, of sulphate of soda making, and for dissolving coprolites and other native phosphates, the acid just alluded to is quite pure enough. At my suggestion, a Glover concentration tower has been constructed at the Hauthaus

In this case 10 lbs. of coke was used for each analysis, and was digested well, first with distilled water, and then with pure hydrochloric acid. The towers had been in use for about a year.

TABLE III.

Air in Flue leading from Condensing Tower to Chimney.

Amount of air taken for each analysis = 500 cubic feet.

Amount of air passing = 31'722 cubic feet per hour.

The mean of 12 analyses is here given.

Arsenic Trioxide per 1000 cubic feet.	Arsenic Trioxide per hour.	Arsenic Trioxide per day.
Grains.	Grains.	Grains.
0'158	5'012	115'134

The arsenic will probably escape either as arsenious acid or as arsenic trichloride. If as the latter, it may be decomposed, on coming in contact with the atmospheric moisture, into arsenious and hydrochloric acid—

TABLE IV.

Specimens of Air, taken 10 feet from Bottom of Chimney.

Amount of air taken for each analysis = 500 cubic feet.

	Arsenic Trioxide per 1000 cubic feet.
Mean of 9 analyses	0'086

The author did not know the amount of air passing in the chimney, so he only calculated the amount of arsenic trioxide in grains per 1000 cubic feet.

The method employed for collecting the arsenic trioxide contained in the last two tables was very simple. The air was drawn through three bottles, containing respectively water, hydrochloric acid, and nitrate of silver. The gas was allowed to bubble very slowly through the solutions. The bottles containing them were capable of holding 40 ounces, and were filled about half full.

The idea of arsenic being present in the atmosphere surrounding chemical works is by no means new. The fact of its existence in large amounts in the ore from which the greater proportion of our vitriol is made leads one to suppose that it must find its way into the atmosphere at one place or another, but the author believes that this is the first time the comparative amounts have been brought forward.

"On Animal Life in Water containing Free Acids," by H. A. SMITH, F.C.S. Communicated by Prof. ROSCOE, F.R.S.

At a time when so much is being written concerning animal life, its origin, and the conditions under which it can exist, it was thought it might be interesting to find out to what extent it was influenced by the presence of free acid in the water in which it existed, and also to see to what extent free acid prevented its origination.

The animals upon which the experiments were tried were the rotifers (*Rotifer vulgaris*).

A certain amount of air was washed with distilled water, and life allowed to originate in the solution, so that it could be seen at once what influence the amount of acid usually found in air had upon the life.

As a rule it required five days to bring the rotifers to perfection. The method of experiment was very simple. After animal life had been procured in the solution, a known amount of the various acids used was then added, and allowed to stand one day: this was repeated till enough had been added to destroy life.

The results of these experiments are embodied in the following tables:—

TABLE I.

Sulphuric Acid added.

Time allowed to stand.	Total Acidity.	Remarks.
Days.	Grms. per Litre.	
5	0'065	Animal life very abundant. Rotifers in very active condition.

Time allowed to stand.	Total Acidity.	Remarks.
Days.	Grms. per Litre.	
6	0'084	No perceptible difference in appearance of life.
7	0'097	Brownish shade evident in water. Want of clearness in portion examined. Small "clots" of vegetable matter visible. Rotifers languid, seemingly disinclined to move.
8	0'153	Life continued for about an hour; all traces then disappeared. The water presented the appearance of being filled with decomposing and decaying organic matter, which was floating about in "shreds."

TABLE II.

Hydrochloric Acid added.

Time allowed to stand.	Total Acidity.	Remarks.
Days.	Grms. per Litre.	
5	0'0085	Same as in Table I.
6	0'0109	No perceptible difference in the appearance of solution.
7	0'0180	No difference observable.
8	0'0190	Life almost immediately extinct. Fluid still clear. Bodies of rotifers seen floating in it, but of a dull opal-like colour, and being rapidly acted upon by the acid, seemingly becoming "shredded."

TABLE III.

Sulphurous Acid added.

Time allowed to stand.	Total Acidity.	Remarks.
Days.	Grms. per Litre.	
5	—	Life very abundant.
6	0'002	Rotifers more active, causing great disturbance in liquid.
7	0'004	Life sluggish. Rotifers not inclined to move.
8	0'010	After 3 hours all life extinct. No obvious action on the bodies of animals.

It is very interesting to compare these three tables. The order of deleterious influence on animal life being first sulphuric, then hydrochloric, and sulphurous acids in order, the action of the two latter being much more distinctly marked than the action of the former.

In making observations on the amount of free acid required to prevent origination of life, it is found that the order of acid is the same as above, but that the line is much more sharply drawn.

TABLE IV.

Experiments on the Amount of Free Acid contained in Water in which Animal Life can originate.—Sulphuric Acid added.

Time allowed to stand.	Total Acidity.	Remarks.
Days.	Grms. per Litre.	
8	0'070	Life abundant.
20	0'074	Little or no life.
26	0'080	No life.

TABLE V.

Hydrochloric Acid added.

Time allowed to stand.	Total Acidity.	Remarks.
Days.	Grms. per Litre.	
5	0'0085	Life abundant.
8	0'0090	No life.

Water acidified with 0.0025 grm. sulphurous acid per litre was allowed to stand exactly under the same conditions as the former, to see if life could originate in water containing that amount of acidity, but after standing twenty-one days no life was visible.

It is interesting to notice, in these last two tables and the remark on sulphurous acid, the sharp line of demarcation between the amount of acid contained in water in which life can originate and that which totally prevents origination.

In the case of sulphuric acid we find that the small amount of 0.010 grm. per litre, in addition to the ordinary acidity, completely prevents it, whilst in the case of hydrochloric acid 0.005 grm. per litre is sufficient. In the case of sulphurous acid the author could not get life to originate in water containing any of that acid.

CORRESPONDENCE.

NEW PROCESSES FOR ANALYSING COMPOUND ETHERS.

To the Editor of the Chemical News.

SIR,—Dr. Dupré's letter of last week calls for reply. I perceive that he does not lay claim to the method of dealing with fats by means of an application of Erlenmeyer's process with hydriodic acid, whereby iodide of isopropyl is formed; but that he claims to have described the process of decomposing the ethers with alkali, and subsequently estimating the alcohol set free. This he claims to have done in his paper on Wines, published in the year 1867.

I think most chemists will agree with me that in the year 1867, as at the present time, there could be no originality in the abstract statement that compound ethers admit of having the alcohol, which they yield to alkalies, measured or weighed. Doubtless original papers by chemists contain such a statement, and most probably it has been made in chemical lectures, and even in answers by students to examination papers. In 1867, as at present, all that was open to a chemist was to remind his brethren of the abstract possibility of such a process, and to point out how to do it and the advantages of resorting to it. Among these advantages I maintain that it is eminently practicable, and capable of yielding very accurate results. As I said in Brighton, I believe that in point of accuracy it will rank with the very best chemical determinations. Notoriously it is not in general use among chemists who are engaged in researches to which it is applicable, and my object in bringing it forward was to induce chemists to use it.

I hope Dr. Dupré will not be offended at being told that, whatever the merits of his paper on wines may be, it has neither induced chemists to adopt the process in question nor was it calculated to do so. Curiously enough, the volatile ethers in wine do not admit of determination by this process. A volatile ether, mixed with several hundred times its weight of alcohol, as occurs in wine, is not under suitable conditions for a determination of the alcohol furnished by decomposing it with alkali; and chemists trying to make such a determination would find themselves exposed to the risk of having the error of experiment greater than the total quantity to be determined. (Unfortunately the evil precedent of a very distinguished chemist has rendered abortive analyses of this description not altogether unfamiliar in England).

In Dr. Dupré's paper I find that he determined the acid of volatile ethers by the usual process, but not a single instance of his having determined the alcohol of a volatile ether; neither can I find any directions for making such determinations, and I will add that it is creditable to Dr. Dupré that he has given none. The non-volatile ethers

in wine Dr. Dupré has indeed analysed by measurement of the alcohol, instead of by the usual process of measuring the acid; but, curiously enough, his experiments on the non-volatile ethers of wine illustrate not the ease and accuracy of the method in question, but the difficulties with which it is beset in exceptional cases. He tells us that the alcohol was too weak to be submitted to the ordinary method of measurement by its specific gravity, and that he had to resort to titrations founded on the method of limited oxidation.

If, when I read my paper in Brighton, I had made a reference to Dr. Dupré's work on Wine, it would have been proper for me to have told the chemical section that—notwithstanding the circumstance that the volatile ethers in wine do not admit of being dealt with by the new process, and notwithstanding the difficulties which Dr. Dupré had found in dealing with the fixed ethers in wine by the process—still, under ordinary circumstances, it is practicable, easy, and accurate, not only in the instance of the fixed ethers, but also of the volatile ethers.—I am, &c.,

J. ALFRED WANKLYN.

RED COLOUR SOMETIMES OBSERVED IN WHITE-LEAD.

To the Editor of the Chemical News.

SIR,—In your "Chemical Notices from Foreign Sources" (vol. xxvi., p. 35), you quoted with well-deserved commendation the results of the labours of Messrs. A. Bannow and G. Krämer upon the red colouration sometimes observed in white-lead. Having procured the original communication and carefully considered the experiments these gentlemen have made, although admiring the industry and ability displayed, I must entirely dissent from their conclusions. I also regret that my contribution to the *Philosophical Magazine* in May, 1869, upon this subject appears to have escaped their notice.

My results, which were procured with all the advantages of experiments in a large manufactory, led most decidedly to the conclusion that silver in certain quantities, commencing at about 0.002 per cent, imparts a uniform pink colour to white-lead corruptions. This conclusion accords completely with practical results, and its truth may be readily tested. Provided the sample of commercial soft lead is free from antimony, and that it contains 0.005 per cent of silver, the corrosion will certainly be pink. The depth of the colour is influenced by the character of the corrosion. In a hard flaky corrosion the colour is worse; where the corrosion is swelled and soft the tint is naturally less, owing to the fine particles of silver being spread over a larger surface.

I have made synthetic experiments as follows:—A sample of lead which had repeatedly produced good white corruptions was melted, and a small portion of pure silver added. On submitting these samples to the corroding action in the stacks, only red-tinted corruptions could be obtained, no matter in what position of the stacks they were placed. The addition of antimony again will produce a dull purple-coloured corrosion; but, upon re-oxidising the antimony, the next corrosion will reproduce the pink colour.

Of the samples of lead submitted to experiment by Messrs. Bannow and Krämer, only No. 5, in my estimation, has sufficient silver to produce the tint in a marked degree; but traces of the colour may be often observed close to the core of uncorroded lead, when the bulk of the corrosion is of a fair white colour.

I ought to add that for some time I was convinced this red colour was due to cuprous oxide, and, indeed, I published this opinion in 1862. Subsequently, after refining a large quantity of lead by the zinc process, I had at command a quantity of lead containing only a trace of copper and other metals, but still retaining about 0.005

per cent of silver. I found I could obtain with this lead nothing but pink-coloured white-lead.—I am, &c.,

WILLIAM BAKER,
Associate Royal School of Mines, London.

Chemical Laboratory,
46, High Street, Sheffield.

CONSTITUTION OF MATTER.

To the Editor of the Chemical News.

SIR,—Without commenting upon Mr. Kingzett's paper, permit me to draw his attention to two points, the inaccuracy of which does not strengthen his illustrations respecting the atomic and molecular influence exerted by the various cosmic forces. The radical methyl is not CH_3 , but is C_2H_6 . There is no proof whatever that methyl and ethyl hydride are not identical bodies. Their reactions are identical; their specific gravity, solubility, &c., are practically identical, and they yield the same dichlor. substitution product. Their mode of formation is sometimes in favour of the one view, sometimes of the other. Schlorlemmer's experiments offer proof in the same direction.

It is therefore not correct to say, that "from the radical methyl we can produce its compounds, but we cannot produce them from ethyl hydride."

Again, propylic alcohol has *not* the same composition, and is *not* isomeric with acetone: it is not surprising, therefore, that they should possess dissimilar properties.—I am, &c.,

J. W.

CONSTITUTION OF MATTER.

To the Editor of the Chemical News.

SIR,—In his paper on the "Constitution of Matter" (CHEMICAL NEWS, vol. xxvi., p. 138), Mr. Kingzett says—"If by some operations a certain substance had its properties changed, the question arises, Should it still be regarded as the original substance?" Mr. Kingzett thinks not. What a glorious chance would this afford to amateur chemists who wish to distinguish themselves by the discovery of new substances! Let them take a beaker of pure water at about 0°C ., and heat it gradually to 100° , marking down in their note-book the discovery of a new substance for every intermediate degree.

"That many simple bodies have properties very much like those of each other," as exemplified by bromine, chlorine, and iodine, is no proof of the mono-elemental theory of matter, but (observing the relations between the gradation of properties and the gradation of atomic weights) is strongly in support of the atomic theory, which stands opposed to the theory advocated by Mr. Kingzett.

"See," says Mr. K., "how the metallic bodies fade into the non-metallic bodies, and animal into vegetable life." Such an abstract idea as this is of no use in a discussion on physical or chemical science, its relation to the subject being too ill-defined to serve as the basis of a thought.

Mr. Kingzett advances the idea that "all the simple known and unknown substances . . . are composed of the same, and only elemental matter, each being differently acted upon by natural molecular forces." We have no doubt that the only difference between the so-called elements (hydrogen, oxygen, &c.) is the difference of their respective atomic weights, and of course corresponding atomic sizes. And, if this is the case, the ultimate atoms themselves (whether of hydrogen, oxygen, or of any other element) must be all of the same, and only elemental matter, because, not being themselves composed of atoms, no difference in the nature of their substance can exist. Thus far we agree with the mono-elemental theory.

Mr. K., having this theory firmly fixed in his mind, has,

through it, fallen into a great error. He supposes that all the so-called elements, being composed of only one primordial matter, there is no chemical difference between them but which may be reconciled by the withdrawal or alteration of the forces. But, inasmuch as the withdrawal of the forces cannot alter the atomic sizes, the chemical nature of the elemental bodies cannot thus be altered.

"On this view of the matter," says Mr. Kingzett, "a compound would be formed by setting a force between two or more such differently operated upon portions of elemental matter."

Under this supposition the compound formed from two elements is, to use the Hibernian style of phraseology, as much an element as either of the substances from which it was formed; the only difference consisting, not in the different absolute amount of forces, but in the forces being brought to operate upon the whole combined mass of matter in a mean of the difference in which they existed in the uncombined elements.

But how is it that when this average force is attained it can never be divided to form substances of indefinite atomic proportions? How is it that the mean of force attained never equals the amount of force contained in any of the elements, or never equals the mean attained by the union of other elements?

Your correspondent asks himself the question, "How do you suppose matter to have been operated upon so as to form different kinds?" He replies by saying, "The forces which constitute the causes were created at the same time as matter was." If heat and electricity are what he calls "the forces," what an idea it is on his part to suppose that these imponderables could remain unequally distributed in matter from the time that matter was created! True it is that different substances are known to contain different quantities of latent heat, and that this latent heat is not diffused from one body to another, even when they are placed in contact; but this depends on the *different atomic weights* of the bodies, and is not observed in bodies of the same nature.

Mr. Kingzett thinks that since the forces are capable of transformation, matter must also be; and considers this idea strengthened by the fact that matter and force are inseparable.

This appears to be a confusion of ideas. That matter and force are inseparable in a physical position is no proof that they are inseparable in physical nature.

How splendidly Mr. Kingzett reveals his want of faith in the tenets of his own philosophy! For, says he, "When iodine is used as in *potassic iodide* it is under a peculiar force known as chemical affinity which masks the property which it possesses when free." Mr. Kingzett's philosophy requires him to believe that when two elements are united as compounds they are entirely destroyed as elements, and only form another element under a different molecular force. Yet here we have Mr. Kingzett confessing that in *potassic iodide* the iodine exists in its own nature; but under a peculiar force, which masks the property which it possesses when free!

That the difference between ethylic hydride and the radical methyl is merely one of molecular arrangement is obvious (apparently), but the sphere of organic chemistry is no fit place to look for the grounds of an argument; it being so infantile and so rapidly growing a science, and the causes which regulate organic combinations being buried in such profound obscurity.—I am, &c.,

JOHN F. SUTTON.

MISCELLANEOUS.

Agricultural Instruction.—At Proskau, which is situated in Upper Silesia, Prussian territory, is established an agricultural college on a large scale, in which everything relating to agriculture, horticulture, sylvestriculture, and the rearing of cattle, horses, bees, and poultry is

practically taught. In addition to several smaller lecture-rooms, there are two large amphitheatres, which will accommodate 200 students each; three separate chemical laboratories; a large distillery; beet-root sugar work; model brewery; museum for mineral and botanical collection; collection of agricultural implements; library containing 6000 volumes; four farms; 5000 hectares of forest land, and 4000 hectares (=2.47 acres to the hectare) of arable meadow land are attached to this institution, in which instruction is given by a staff of twenty-four professors. Proskau is situated very near to the Russian (Poland) frontier, and in the neighbourhood of the town several industrial establishments exist, lime-stone burning and pottery making being very largely represented. The institution alluded to is state property, and has been arranged like the institution known as Hohenheim, near Stuttgart (Wurtemberg). Proskau has 1900 inhabitants, of whom 1500 are Poles.—*Moniteur Scientifique*.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 30, 1872.

This number contains, in addition to several original papers relating to physics, mathematics, astronomy, and natural history, the following original papers more particularly relating to chemistry:—

Stability of Dyes Fixed on Woven Fabrics in general, and more particularly on Silk.—Professor Chevreul.—This lengthy essay, elucidated by tables exhibiting results of experiments, treats on the stability of dyes imparted to silk, more particularly damasks and fabrics used in furnishing. The blue colours produced by indigo are fast and stable; Prussian blue resists moderately the action of air and light, but not of soap; scarlets and carmines produced by cochineal and lac-dye are fast; the fastest yellows on silk are produced by weld.

Researches on the Anti-Ferment Properties and Physiological Action of Silicate of Soda.—A. Kabuteau and F. Papillon.—After briefly referring to the researches of Prof. Dumas on the action of borax in fermentation (*CHEMICAL NEWS*, vol. xxvi., p. 82), the authors describe at length a series of experiments made with the view of ascertaining the effect of silicate of soda upon alcoholic fermentation, upon the fermentation of urea, upon lactic fermentation, and upon amygdalic fermentation. It appears that silicate of soda acts in a similar manner to borax, but far more energetically; not only does it prevent fermentation, but it is a strong disinfectant, and its physiological action, when injected in the blood in aqueous solution (1 to 40), is fatal to animal life, while such is not the case with borax under similar conditions.

Report of the Committee Appointed to Investigate the Alteration Produced in Bread, whereby there is Formed in it Oidium Aurantiacum.—F. Rochard and Ch. Legros.—This memoir treats on the causes of the formation of peculiar cryptogamic plants in bread, and on the precautions to be taken to prevent this injury, which is mainly due to the use of inferior materials, a badly conducted process of preparation, and insufficient baking of the bread. The authors do not consider that the *O. aurantiacum* is injurious to animal life, because rats largely fed with it have not suffered in health; with due precautions, the use of sound materials, and proper methods of preparing and baking bread, this formation may be entirely prevented, but the addition of a larger proportion of salt will not remedy the evil.

Bulletin de l'Académie Royale des Sciences, des Lettres et de Beaux Arts de Belgique, No 8, 1872.

This number contains the following original papers relating to chemistry:—

Researches on Camphors.—E. Dubois.—This paper is the first instalment of a lengthy essay, recording the results of experiments with which the author is still engaged. The object of this investigation is the study of the chemical structure of camphors. This portion treats on the action of pentasulphide of phosphorus upon monobromated camphor, the object being to obtain bromated cymol. At the ordinary temperature pentachloride of phosphorus (first tried

by the author) does not act upon monobromated camphor; at 100° there is no apparent action; at a still higher temperature, scarcely any action is noticed. 1 molecule of pentasulphide of camphor and 5 molecules of the monobromated camphor being heated together on a sand-bath, a very tumultuous reaction occurs, and partial carbonisation of the organic matter ensues. The result of this reaction is chiefly crude cymol, which, on being purified, and having been converted into cymol-sulphate of barium, yielded, by elementary analysis, the following percentage composition:—Carbon, 42.63; hydrogen, 4.62; barium, 24.33; sulphur, 11.37; oxygen, 17.04. Formula—

In addition to cymol, there are formed by this reaction small quantities of hydrocarbons of the same series, and an organic sulphhydrate soluble in alkalis.

Report on the Thunderstorm during which the Turret of the Railway-Station at Mechelen (Malines) was Struck by Lightning.—A. Fassioux.—The author, director-general of the railways (State property), post office, and telegraphs of Belgium, gives a detailed account of the curious effects of the striking by lightning of the clock-turret of this large building during a thunderstorm in July last.

Les Mondes, October 3, 1872.

International Congress on the Metric System.—The States represented at this meeting are—The United Kingdom, France, Russia, Germany, Austro-Hungary, Spain, Belgium, the Netherlands, United States, Argentine Republic, Bavaria, Chili, Columbia, Denmark, Republic of Ecuador, Greece, Haiti, Peru, Portugal, San-Salvador, Sweden and Norway, Turkey, Venezuela, Wurtemberg, Italy, Nicaragua, Switzerland, Uruguay, and the Saint-Siège. It is confidently hoped that a great step in advance will be made for realising what is highly desirable, the unification of weights and measures for different countries. The United Kingdom is represented by the Astronomer-Royal; Dr. H. W. Miller, of Cambridge; and Mr. Chisholm, the Keeper of the Standards. The Rev. Father A. Secchi, S.J., represents the Saint-Siège.

Meteorological Observatory on the Summit of the Puy de Dome.—Rev. F. Moigno.—It appears that the necessary arrangements are made for the immediate establishment of two meteorological observatories—one on the summit of this mountain, situated close to Clermont-Ferrand, in the Department of the Puy de Dome, Central France, the other in the town just alluded to—both to be in telegraphic communication; the difference in altitude between these localities is 1160 metres. Clermont is situated at about 450 metres above sea-level.

Hydro-Electric Submarine Cable.—F. Tomasi.—Illustrated by a series of woodcuts.

Spectroscope with Slide.—M. Hofmann.—The description, illustrated by woodcuts, of an improved spectroscope constructed by the author, of which it is stated that, having been lately inspected by Dr. Tyndall, Mr. Wright, Father Secchi, and others, it has been highly approved of by them.

Although not strictly belonging to chemistry, we call attention to the contents of the following paper:—

Geographical Works.—A. Marie.—The author, Professor at the Normal School of Carlsbourg (Belgium), has invented a greatly improved method of making maps and charts, termed hypometrical, whereby the countries which are exhibited are shown as they are in their natural state, so that a sound idea of the real configuration of the land, rivers, lakes, mountains, &c., is given at a glance.

Bulletin de la Société Chimique de Paris, August 15, 1872.

This number contains the following original papers and memoirs:—

Essay on the Phosphoplatinic Compounds.—P. Schützenberger and E. Fontaine.—The third instalment of this exhaustive monograph; it contains the following sections:—Action of zinc on the ethyl-phosphoplatinous (*platineux*) ether; amyl-phosphoplatinous ether; action of the phosphoplatinous chloride upon glycerine, allylic alcohol, benzylic alcohol, ammonia, and compound ammonias; phosphoplatinic ethers; methyl-phosphoplatinic ether; ethyl-phosphoplatinic ether. This essay, elucidated by a large number of complex formulæ, is to be continued.

Contribution to the History of Mesoxalic Acid.—J. Ossikovsky.—From chloroxalic ether—

(prepared by the action of oxychloride of phosphorus upon ethyl-oxalate of potassium), by the action of cyanide of potassium, and next saponification of the cyanoxalate of ethyl thus formed, no mesoxalic acid is obtained, the result of the reactions being the formation of oxalic acid.

Acetyloxamate of Ethyl.—J. Ossikovsky and G. Barbaglia.—The authors describe at length the reaction which takes place when a molecule of fused acetamide and 1 molecule of chloroxalate of ethyl are mixed; the final result of this reaction, assisted by heat and purification of the new product, is the formation of a liquid which exhibits the following characters:—It is not precipitated by chloride of calcium; gives off ammonia very abundantly when boiled with concentrated caustic soda solution; nitrate produces a feeble opalescence not dissolved by nitric acid; treated with boiling water,

it yields a large quantity of acetic ether, which volatilises; while, on evaporation, the solution yields acid oxalate of ammonium—

By distillation, the substance (acetylloxamate of ethyl) is decomposed, depositing carbonaceous matter, while acetic ether and acetamide are produced in small quantity; on being kept for a long time, the liquid deposits crystals, which, on analysis, yield results leading to the formula—

Researches on Guanidine.—J. Ossikovszky.—The author describes at length a method of preparing guanidine as directed by Bannow, and consisting in heating iodide of cyanogen with three times its weight of ammoniacal alcohol (to 10 per cent NH_3) in sealed tubes, followed by a lengthy and rather tedious process of purification; it appears that there is simultaneously formed a fatty acid (probably propionic acid), which, however, was not obtained by the author in free state. Guanidine is, while taking up the elements of water under the influence of hydrate of baryta, readily converted into ammonia and urea, or into the products of decomposition of the latter, viz., carbonic acid and ammonia.

Action of Salts of Lime upon a Decoction of Cochineal.—E. Guignet.—A black-coloured carminate of lime is obtained by treating carminic acid or a decoction of cochineal with a solution of bicarbonate of lime, whereby an abundant precipitate is formed, which is insoluble in water and alcohol, and yields with lime-water a violet-coloured basic carminate of lime; while, when the black carminate is heated along with a solution of neutral acetate of lead, there is formed a bluish-violet coloured carminate of lead. It is necessary to employ in these reactions lime salts quite free from iron, because the decoction of cochineal is precipitated by the salts of that metal, yielding with it black-coloured compounds. It appears that the action of salts of lime upon cochineal is so characteristic that it may be used as a test for lime; the author states that several commercially-sold products, such as glue and starch, for instance, which have been prepared with lime salts containing water, are coloured black by a decoction of cochineal.

Pyrogenic Oils of Pechelbronn (Alsace).—J. A. le Bel.—The exhaustive and detailed description of various products (hydrocarbons) obtained by fractional distillation from the petroleum oil prepared from the bituminous shale met with at the locality alluded to; the author also gives a description of a distillatory apparatus invented by him, and contrived for the purpose of rendering fractional distillation a more readily managed and continuous operation.

Note on some Unfinished Experiments Relating to the Reciprocal Transformation of Dextro- and Levo-Tartaric Acid.—Lecoq de Boisbaudran.

Oxidation of Sugar by means of Permanganate of Potassa.—J. Mauméné.—By this oxidation there are formed two acids—Hexépico, $\text{C}_{12}\text{H}_{13}\text{O}_{16} = \text{C}_6\text{H}_{11}\text{O}_{16}\text{HO}$; and triépico— $\text{C}_6\text{H}_8\text{O}_{10} = \text{C}_6\text{H}_8\text{O}_9\text{HO}$.

The author points out in the following manner the relation existing between hexépico acid and acids already long known:—

Hexépico acid,	$\text{C}_{12}\text{H}_{13}\text{O}_{16}$
Saccharic acid,	$\text{C}_{12}\text{H}_{20}\text{O}_{16}$
Malic acid,	$\text{C}_{12}\text{H}_{14}\text{O}_{16}(\text{C}_6\text{H}_8\text{O}_{10} \times 1\frac{1}{2})$
Tartaric acid,	$\text{C}_{12}\text{H}_{12}\text{O}_{16}(\text{C}_6\text{H}_8\text{O}_{10} \times 1\frac{1}{2})$
Carbomethylic acid,	$\text{C}_{12}\text{H}_{14}\text{O}_{16}(\text{C}_6\text{H}_8\text{O}_9 \times 3)$

Le Moniteur Scientifique Quesneville, No. 370, October, 1872.

This number only contains the two following original communications:—

Estimation of Lithia in Mineral Waters.—F. Wurtz.—As it is difficult to entirely separate lithia present in mineral waters from lime, the following method was applied by the author, while analysing the mineral water of the Madeleine spring of Vals:—15 litres of the water are first evaporated to one-tenth of the original bulk, and the liquid is next filtered, for the purpose of eliminating carbonate and sulphate of lime and earthy matters deposited during the evaporation. To the filtrate is added perfectly pure carbonate of soda in slight excess, in order to precipitate earthy matters kept in solution; after this, the liquid is evaporated to dryness, the residue is treated with boiling distilled water, and the liquid is filtered while hot into a small porcelain or platinum crucible placed on a water-bath. To the hot filtrate, phosphate of soda is added, whereby the carbonate of lithia, hitherto kept in solution, is precipitated as phosphate of lithia, which, with the liquid therein it is suspended, is evaporated to dryness; the residue is next treated with cold water, and the insoluble salt is thrown on a filter, and, after drying, weighed. In order to test whether there is any phosphate of lime mixed with the phosphate of lithia, the latter is dissolved in perfectly pure and dilute sulphuric acid, care being taken to use no more acid than is just required, according to the weight of the phosphate of lithia obtained. This solution is next treated with neutral acetate of lead, forming insoluble sulphate and phosphate of lead, while acetate of lithia and acetate of lime (supposing the lithia salt to have been still contaminated with lime) are kept in solution; the excess of lead is removed by sulphuretted hydrogen, and the liquid again filtered; some pure and dilute sulphuric acid is again added to the filtrate, and the liquid again evaporated to dryness upon a water-bath. The sulphate of lithia is next treated with boiling

alcohol, in which any sulphate of lime which happens to be present is insoluble; the alcoholic solution, previously filtered if the sulphate of lime was present, is lastly evaporated to dryness, and the sulphate of lithia weighed.

Preparation of Alcohol from Sawdust.—M. Zetterlund.—Into an ordinary steam-boiler, heated by means of steam, were introduced 9 cwts. of very wet sawdust, 107 cwts. of hydrochloric acid (sp. gr. = 1.18), and 30 cwts. of water; after eleven hours' boiling, there was formed 19.67 per cent of grape sugar. The acid was next saturated with chalk, so as to leave in the liquid only a small quantity (4 degrees by Luedersdorf's acid areometer); when the saccharine liquid was cooled down to 30°, yeast was added, and the fermentation finished in twenty-four hours. By distillation, there were obtained 26½ litres of alcohol of 50 per cent at 15°, quite free from any smell of turpentine, and of excellent taste. It appears that the preparation of alcohol from sawdust may be successfully carried on industrially when it is precisely ascertained what degree of dilution of acid is required, and how long the liquid has to be boiled. When all the cellulose present in sawdust might be converted into sugar, 50 kilos. of the former substance would yield, after fermentation, 12 litres of alcohol at 50 per cent.

Bibliography.—Under this heading we quote the title of a work which is highly spoken of:—"Précis de Chimie Légale; Guide pour la Recherche des Poisons, l'Examen des Armes à Feu, l'Analyse des Cendres, l'Altération des Ecritures, des Monnaies, des Alliages, des Dénrées et la Détermination des Tâches dans les Expertises Chimico-Légales; à l'Usage des Médecins, Pharmaciens, Chimistes, Experts, Avocats, &c.," par A. Naquet, Professeur Agrégé de la Faculté de Médecine de Paris; avec 18 figures dans le texte; 1 vol. in 18. Paris, chez Savy, Libraire, Rue Hautefeuille, No. 24; prix, 3 francs.

Sitzungsberichte der Mathematisch-Physikalischen Classe der Königlich Bayerischen Akademie der Wissenschaften zu München, No. 1, 1872.

In addition to several original memoirs relating to natural history, anatomy, geology, and physics, this number contains the following original papers and memoirs relating to chemistry:—

Products of the Decomposition of the Quecksilberfahlers of Moschellandsberg in the Pfalz.—F. Sandberger.—The mercury ore which is met with in Rhenish Bavaria has an iron-grey colour, a metallic lustre, a sp. gr. of 5.095, and consists, in 100 parts, of:—Sulphur, 21.90; arsenic, 0.31; antimony, 23.45; bismuth, 1.57; copper, 32.19; mercury, 17.32; iron, 1.41; cobalt, 0.23; zinc, 0.10; gangue, 1.39. There is met with at the same locality another quecksilberfahler (the German name is retained in Dana's "System of Mineralogy"), the sp. gr. of which varies from 5.509 to 5.511, while, in addition to its containing 24.1 per cent of mercury, it also contains 5.62 per cent of silver. The author treats, further, on the spontaneous decomposition of the first-mentioned ore, and states that, according to his investigation of the weathered mineral, no loss of mercury ensues.

Influence of Absolute Alcohol upon some Chemical Reactions.—Dr. Vogel.—The author records in this paper a series of reactions which are modified, or even entirely suspended, by strong alcohol, in consequence of the insolubility in that fluid of many substances which are soluble in weaker alcohol and in water. Two reactions are more particularly alluded to, viz., that of starched test-paper and tincture of iodine, and the behaviour of metallic potassium with strong (absolute) alcohol. When potassium is put into a basin containing alcohol stronger than 0.823 sp. gr., no ignition of the metal takes place, which is, however, oxidised, and rotates as it does when thrown upon water; when thrown upon alcohol of 0.830 sp. gr., ignition takes place.

Action of Active Oxygen upon Pyrogallol Acid.—H. Struve.—This lengthy essay treats on the action of peroxides and other oxidising substances upon pyrogallol acid alone or in the presence of gum, blood, saliva, malt extract, &c. It appears that pyrogallol acid yields several coloured products of oxidation, among which purpurogallin is one of the most prominent.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents, 54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2450. F. Lipscombe, Strand, Middlesex, "Improvements in the treatment of noxious vapours, and in apparatus or appliances in connection therewith."—Petition recorded August 16, 1872.

2518. W. Lockhead, Glasgow, N.B., "Improvements in treating asbestos or amianthus and applying the same to various useful purposes."—Petition recorded August 24, 1872.

2576. G. Spencer, Cannon Street, London, "Improvements in the purification of coal gas used for illuminating purposes and for mechanical purposes, and in apparatus therefor."—A communication from E. White, New York, U.S.A.—Petition recorded August 30, 1872.

2614. B. W. Gerland, Macclesfield, Cheshire, "Improvements in the manufacture of phosphoric acid, phosphatic manures, alkaline, and other phosphates."—A communication from H. and E. Albert, Biebrich, Germany.—Petition recorded September 3, 1872.

NEW PROCESS FOR THE MANUFACTURE OF IODIDE OF POTASSIUM FROM THE MOTHER-LIQUORS OF KELP.*

By E. SONSTADT.

This process consists in converting the alkaline iodides, contained in the mother-liquors from kelp, into iodates; precipitating the iodic acid by a soluble barium salt; heating the precipitate with solution of sulphate of potassium, which gives iodate of potassium in solution; drying up and melting the iodate of potassium solution, and crystallising the solution of the melted iodide of potassium thus obtained.

The conversion of iodides into iodates in the mother-liquors is effected by one of the following processes. But it is advisable, first, to partially or completely precipitate the sulphuric acid from the mother-liquor by solution of chloride of barium or other suitable barium salt, as thus silicic acid, if present, and other impurities are separated, and the precipitate afterwards obtained of iodate of barium is more manageable. The mother-liquor is then, after separation of the precipitate, melted, to destroy organic matter. The melted mass is dissolved in water, and the solution, after separation from the residue, is, if intended for treatment by any of the processes except the last undermentioned, rendered alkaline by addition of a caustic or carbonated alkali, to such extent that the liquid may contain, for each atom of an iodide in it, five atoms of a caustic alkali, or ten atoms of a carbonated alkali. The liquid thus prepared may then be treated by any of the following processes for conversion of the iodide in it into iodate.

(1.) Chlorine is passed through the liquid until the whole of the iodide is transformed into iodate, but no longer.

(2.) Solution of a permanganate is added until a slight permanent colouration of permanganate remains. The liquid is then separated from the manganese precipitate, which latter may be furnished with soda, or with soda and nitre, to re-form permanganate for another operation.

(3.) By passing an electric current through the dilute solution in the way usual in electrolysis. This process would be convenient and economical where the electricity can be obtained from electro-magnetic machines worked by water-power.

(4.) In this process, the purified mother-liquor is dried up with addition of an atom of an alkaline chlorate for each atom of an iodate present. The mixture is then cautiously heated below redness until the iodide is converted into iodate.

After the iodic acid is separated from the mother-liquors, the bromide remaining in solution may be converted into bromate by either the processes (1) or (4), and bromide of potassium, obtained by the same methods as used for obtaining iodide of potassium. Processes (2) and (3) are not applicable to the formation of bromate.

ON THE OCCURRENCE AND DETECTION OF VANADIUM AND TITANIUM IN TRAP-ROCKS.

By RICHARD APJOHN.

WHILE working in the Bonn Laboratorium, under the late Professor Engelbach, he mentioned to me that he had

* Patent No. 1054, April 10, 1872.

found vanadium and titanium in the trap-rock which occurs in the adjacent Rhine district. Since then, on considering the subject, it seemed to me that it would be a matter of interest to extend the investigation further, and to operate on a number of different specimens of trap-rock. I accordingly undertook, with this object, a series of experiments, which I shall now briefly describe. Three different basalts were made the subject of examination, viz., one from a trap-dyke at Dunamoe, County Wicklow, one from the Giant's Causeway, and one from Vicentine, Italy.

Process for Detection of Vanadium.

Eight grammes of the finely-powdered mineral was fluxed with four times its weight of carbonate of sodium. The fused mass was then allowed to cool, and a small quantity of nitre was added. It was now heated over the Bunsen's lamp, taking care that the crucible did not attain more than a dull red heat. The mass was lixiviated with water, and the aqueous solution was boiled with carbonate of ammonium, and filtered to remove silicic acid. The filtrate was evaporated with hydrochloric acid, and sulphide of hydrogen was passed in to precipitate any metals of the lead group which might be present. The filtered solution was then treated with an equal volume of very concentrated solution of ammonia, and sulphide of hydrogen was passed in till all the free ammonia was saturated.

In the case of each specimen the solution assumed a beautiful intense cherry-red colour, a sure indication of the presence of vanadium. This coloured liquid was filtered off and saturated with hydrochloric acid; the precipitate, containing sulphur and sulphide of vanadium, was dried and ignited, and the residue was melted with a pinch of nitre. From the vanadate of potassium thus formed the characteristic blowpipe reactions were obtained.

Detection and Estimation of Titanium.

Twelve grammes of the finely-powdered rock were fluxed with six times their weight of acid sulphate of potassium, and the heat was continued until the greater part of the free sulphuric acid was driven off. The cooled mass was reduced to a fine powder, exhausted with cold water, and the aqueous solution (it should be largely diluted) was boiled with acid sulphite of sodium. As soon as the precipitation was complete, the contents of the flask were allowed to cool, and a little sulphurous acid was added to re-dissolve any iron or aluminium which might have been precipitated. This precipitate of titanic acid was converted into the titano-fluoride of potassium in the usual manner, and the salt thus obtained was collected on a weighed filter, washed with a few drops of cold water, dried, and weighed; and from this weight the amount of titanic acid was deduced. With a view to testing the accuracy of this result, the titano-fluoride was dissolved in hot water, and the titanic acid was precipitated by ammonia, ignited, and weighed.

The results obtained in these experiments are given in the following table:—

	K_2TiF_6 .	TiO_2 calculated from K_2TiF_6 .	TiO_2 precipitated by NH_3 .	Per cent of TiO_2 in Trap-rock.
12 grms. of Wicklow trap gave	0.660	0.222	0.190	1.58
12 grms. of Giant's Causeway basalt gave	0.240	0.081	0.084	0.70
12 grms. of Vicentine (Italy) basalt gave	0.325	0.110	0.110	0.91

The titanic acid beads, formed with salt of phosphorus in the reducing flame, exhibited that pure amethyst shade which showed that the iron had been completely separated.

It is interesting to observe how closely the titanic acid calculated from the titano-fluoride agrees with that which was found by precipitation with ammonia. The numbers yielded by the two methods are so nearly the same, that small quantities of titanic acid would, I am sure, be best

estimated by weighing it in the form of titanio-fluoride. Such a course would be recommended by the fact of the atomic weight of the titanio-fluoride being nearly three times that of titanic acid. The modern analyses of trap-rocks are few in number, and but in one (see Watts's "Dictionary," vol. iv., p. 251) is the presence of titanic acid noticed. It appears to me, therefore, a matter of some importance to put upon record the fact that, in the specimens of this rock which I have examined, both of these constituents occur, and in quantities which admit of estimation. The data are probably insufficient to justify the conclusion that these rare elements exist in all trappean rocks; but the results of the experiments which I have made would seem to invest such a conclusion with some degree of probability.

ON THE ABSORPTION OF ATMOSPHERIC NITROGEN BY VEGETATION.*

By M. P. P. DEHERAIN.

NUMEROUS analyses of arable earths now in the possession of agricultural science, have established the fact that there exists in soil a considerable quantity of combined nitrogen, whose origin cannot be attributed to old dressings, inasmuch as M. Boussingault has observed that the amount of nitrogen contained in the vegetation collected during the distribution growth of crops upon a given surface exceeded the quantity contained in the manure which that surface had received. The excess is often considerable, and must be explained either by admitting that plants draw nitrogen directly from the air and fix it in their tissues, or, that in consequence of some reaction as yet but little known, arable earth becomes gradually charged with atmospheric nitrogen, which is then transmitted to the vegetation.

The numerous experiments attempted in France by M. Boussingault, and in England by Messrs. Lawes, Gilbert, and Pugh, in order to ascertain whether plants absorb nitrogen directly from the air, have failed. The production of ammonia or nitric acid by meteoric phenomena, rain, snow, or dew, is scarcely sufficient to cover the loss occasioned by the evaporation of ammonia in the air by the draining of superficial and sub-soil waters, which easily carry away nitrates, and, lastly, by the emission of free nitrogen which is produced during the decomposition of organic matter used as manure. It is therefore evident, *a priori*, that some powerful cause must determine in the soil that fraction of the nitrogen revealed there by analysis. After reflecting upon the various circumstances under which the union of the two elements of the air occurs, it is found to habitually accompany the oxidation of combustible matter; and it seemed to me that oxidation of the organic matter arising from the remains of former vegetation, or from manure, might perhaps produce the combination of atmospheric nitrogen with oxygen.

To render this certain, I resolved to undertake two series of experiments. By the first I have ascertained the absorption of gaseous nitrogen during the oxidation of organic matter. In the second, which will be the subject of a later communication, I examined the nitrogen in combination by endeavouring to point out those reactions which produce the black matter of arable earth. After several attempts, I succeeded in obtaining a regular absorption of nitrogen by the following means. Into a matrass of green glass capable of containing 200 c.c. was introduced a mixture of equal volumes of air and oxygen, whose exact composition had been ascertained, and then a liquid consisting of 15 grms. of glucose dissolved in 15 c.c. of water, and 15 c.c. of common ammonia. This is closed before the blowpipe, and, if the manipula-

tion is rapid, only a very insignificant portion of air can enter the matrass. Even should a larger quantity obtain entrance, the experiment will not be spoiled. The proportion of nitrogen in the matrass will become rather larger than is indicated by the analysis, only a small quantity of the nitrogen absorbed passing unperceived. Heat is applied for 100 hours by the water-bath, and when completely cooled the height of the liquid is marked upon the neck of the reversed matrass, and the end is broken under water. With the preceding proportions the absorption is considerable, nothing but nitrogen remaining. All oxygen and carbonic acid will have disappeared; the gas is collected in a graduated éprouvette, the entire absence of oxygen or carbonic acid is ascertained by potash and pyrogallic acid, and the remaining quantity of nitrogen is read off, the quantity being considerably less than what was introduced. Here are particulars of the two experiments. Of 100 parts of gas introduced, 58.40 consisted of oxygen; 41.60 nitrogen; the liquid glucose and ammonia occupied 30 c.c.; and the gas contained in the matrass 184 c.c. Before the experiment there were 76.5 c.c. of nitrogen in the mixture, when, after heating the matrass, the end was broken under water, only 70 c.c. of gas were found, containing neither oxygen nor carbonic acid. 6.5 c.c. of nitrogen were therefore absorbed, or 8.6 per 100.

In one of the experiments made with the nitrated glucose of M. P. Thenard, and with ammonia, with gas containing 52 of nitrogen to 48 of oxygen, an absorption was ascertained of 11.3 c.c. against 53 introduced, that is to say 21.5 per 100.

Six experiments were made with humic acid mixed with potash, acting upon atmospheric air; and of 100 volumes of nitrogen introduced, an average of 7 volumes was absorbed. Two experiments were made with decayed wood mixed with potash; the introduced gas was rich in oxygen, and 3.6 were absorbed per 100 volumes. Upon substituting ammonia for the potash, no absorption of nitrogen was perceived; on the contrary, at the end of the experiment more nitrogen was found than at the commencement. In twenty of these experiments made with glucose and ammonia acting upon equal volumes of air and oxygen, an average absorption was established of 5.9 c.c. of nitrogen to 100 introduced. Lastly, in four experiments in which a mixture of M. P. Thenard's nitrated glucose with ammonia was employed, an average absorption of 15.4 to 100 of introduced nitrogen was observed.

Thus in the presence of slow combustion of organic matter, atmospheric nitrogen enters into combination, probably to form nitric acid, which, from contact with excess of carbonaceous matter is reduced, and yields its nitrogen to the organic matter. This last reaction has been established by M. P. Thenard, and having verified it, we may, by depending upon it, endeavour to imagine what is the origin of the excess of nitrogen found in plants, and in the soil over the quantity furnished by manures. The conditions under which atmospheric nitrogen is brought into combination require that some organic matter should be consumed in the air; every plant which leaves remains upon the soil which bears it is therefore the means of more or less fixation of nitrogen. This reaction continues during many years, and ends by accumulating upon soil abandoned to spontaneous vegetation, such as waste land, a quantity of nitrogen sufficient to enable a cultivator, after clearing, to obtain several crops of cereals without the introduction of nitrated manure. It is thus that prairies and forests suffice for the regular supply of hay and wood without man's interfering to compensate for the periodical losses to which they have been subject from time immemorial.

The productive powers of the soil of forests and prairies are, however, not to be compared to those of arable land. The vegetable remains left upon the former are not in so favourable a state for combustion as those which form the dressing received by the latter, for we have already seen that the nitrated glucose which occurs during the manu-

* Extract by the Author.

façure of farmyard manure is the most favourable of all mixtures employed for the fixation of atmospheric nitrogen. The action of manure upon vegetation is not due only to the six-thousandths of nitrogen which it contains, but also to the decomposing carbonaceous matter which constitutes the entire mass; when buried in the earth, this matter is preserved there some time if the cultivator does not endeavour to finish its oxidation. To this end he tears the earth with his ploughshare, he aerates it, he is unsparing of his means; under the influence of the air the organic matter burns, yielding those considerable quantities of carbonic acid which the analyses of MM. Bous-singault and Lewy have discovered in the air entangled in the earth. This combustion determines the union of the two elements of the air, and there is added to the nitrogen which the dressing naturally contains, that which, drawn from the atmosphere, is thence conducted through the series of metamorphoses, which transmit it from the soil to the plant and from the plant to the animal.

What are the conditions of composition, aération, and of moisture most favourable to the fixation of atmospheric nitrogen in arable soil? This is an important question, since experiment shows that the circumstances under which the combination of gaseous nitrogen occurs are very clearly defined; it does not take place if oxidation is either too rapid or too slow, and it is probable that nitrogen does not become fixed with the same facility in all kinds of earth. Further study of the subject may lead to development of the conditions most favourable to the accomplishment of this remarkable phenomenon, and thus to ascertaining one of the dominant causes of fertility.—*Comptes Rendus.*

WATER ANALYSIS IN INDIA.

By EDWARD NICHOLSON,

Assistant Surgeon, R.A.; Analyst of Waters, Mysore, Northern and Ceded Districts.

In your columns of the 7th of June (CHEMICAL NEWS, vol. xxv., p. 273) appears a letter from Dr. Macnamara, Chemical Examiner to Government at Calcutta, deprecating my condemnation of the Bengal water analyses made under his superintendence. He states that fifteen years of experience had enabled him to know the peculiarities of Indian waters, that he had fully recognised them, and had caused them to be recognised by his analysts, especially as regards the occurrence of nitrates in unpolluted waters. Now I have looked carefully through seven half-yearly Reports of these analyses, and the remarks made thereon by Dr. Macnamara. I find in them not a trace of any such recognition; on the contrary, I find hundreds of waters condemned because they contain some nitric acid or a rather large amount of chlorides; I even find recommendations that large cantonments shall be abandoned, solely because the amount of these constituents does not please the analysts. I can adduce plenty of facts in support of my assertions, but will content myself for the present with quoting two of Dr. Macnamara's own analyses *in extenso*, so as to show both the chemistry of a scheme elaborated after fifteen years' experience, and the kind of evidence on which waters are condemned.

I may premise by stating that the form of analysis here laid down was obligatory. The "soluble" salts of a water might contain earthy nitrates, sulphates, or chlorides, in addition to alkaline salts, yet they must be given as chloride of sodium, sulphate of soda, carbonate of soda; no deviations were allowed; and an analyst who gave the actual constituents of the water was checked, and ordered to repeat the analysis according to the form ordered.

The two analyses I am about to quote are to be found in the fourth volume of Reports; they will be the best commentary on his statement that "no one would think

of condemning a water simply because it contained a large amount of nitrates or of chlorides."

Wells in Fort William, Calcutta.

	Well near Chowringhee Gate.	Well near Treasury Gate.
Physical properties	good	good

Earthy salts, silica, &c., insoluble .. }	29	14.5
Lime, calculated as carbonate }	18	10
Silica	traces	traces
Soluble salts	37	22
Chloride of sodium	20.5	12.5
Sulphate of soda	5.5	3.6
Carbonate of soda	{ not deter- mined.	{ not deter- mined.

Abstract of Remarks.—These wells are both properly constructed with efficient parapet platform and drain—the first well 41 feet deep, with 6 feet water; the second 29 feet, with 4 feet water. The sepoys who use them consider both waters of good quality. The first well has a bazar 48 feet off; sepoys' quarters are close at hand, and the sepoys bathe and wash their cooking utensils in the vicinity of the well. [I may here explain that a sepoy bathes by throwing a pot or two of water over his head, and then wiping himself dry with his cloth. His cooking utensils consist of a couple of brass vessels, in which rice is cooked and eaten; they are kept beautifully bright by being scoured with sand.] The second well has "no bazar or other permanent source of pollution in the neighbourhood."

I pause, and ask What is the common sense verdict on the above evidence? Two waters, by no means hard if we are to believe the soap-test results, containing a rather large amount of chlorides, a *notable amount of sulphates*, a minimum amount of oxidisable organic matter (.0002 per 1000 of oxygen is the usual permanganate result in good wells), a small amount of nitric acid for India. Water of good physical properties, considered good by the people drinking it. Wells in perfectly satisfactory condition, neither of them very far from a tidal river (Fort William is on the banks of the Hoogly), in an alluvial delta. No source of pollution in the neighbourhood of one; in the other case, none beyond sepoys' quarters and a bazar. People wash near the well (as they do at every well in India).

Common sense verdict:—Good waters, somewhat affected by the saline deposits natural in an alluvial delta; No. 2 but slightly so. In neither case so much as to render them unfit for drinking if the people using them find them good.

Dr. Macnamara's verdict:—No. 2. "No doubt much of the saline matter in the well is derived from the washings of sepoys' bodies and cooking utensils." No. 1. "No doubt their neighbourhood [the bazar and sepoys' quarters], and the constant washing that goes on, not only of bodies, but of cooking utensils, in the vicinity of the well, is the reason of the impurity of the water."

The plain fact is, that Dr. Macnamara knows no other source of chlorine and nitric acid but animal excreta; he has never taken the trouble to ascertain how far washing, &c., at a properly constructed well will pollute the water in it; he has never observed the fact that the presence of sulphates is presumptive evidence of marine origin in the

chlorides present; he simply sees chlorine and nitric acid present, and though every other fact is dead against pollution of the well, he looks about till he sees a sepoy washing his body or his brass plates, and the explanation is found. On reference to the analysts' reports, I can find numerous instances where wells described as "surroundings very dirty," "everything connected with the locality of the well dirty in the extreme," contain less than 2 grains per gallon of chlorides. The slightest powers of observation would have shown Dr. Macnamara that, under an Indian sun (aided by Indian crows),* surface pollution, unless of the foulest character, does not affect the sub-soil water, while sub-soil pollution, such as that of cess-pits, &c., exercises a most striking influence. I render every justice to Dr. Macnamara's industry and zeal; he, however, lacks at least one qualification necessary to the analyst of waters, the faculty of observation.

What can be expected of analyses made according to the form I have quoted? Let any one compare the following points in them:—

	No. 1.	No. 2.
Total hardness, degrees	6.1	9.8
Lime calculated as carbonate, grains	18	10
Mag. carb. (by difference)	11	4.5
Total insoluble earthy salts ..	29	14.5

These are analyses made by the author and superintendent of the system; the character of those made by the analysts can readily be imagined.

As a rule, the only waters that escaped condemnation were river waters, as they cannot contain nitrates in sufficient quantity to be detected by the rude qualitative estimation ordered by Dr. Macnamara, and no amount of pollution seems to increase their chlorides. But when we come to the wells, the havoc played amongst them by the analysts is terrible; with a few exceptions, they seemed to vie with one another in piling up sanitary horrors. Here is a specimen, taken at chance, of a well-water in a rather brackish district, as may be told at once by the quantity of sulphates present:—

Well No. 11, Dinapore.

Physical qualities	good
Total hardness	8.47
Permanent ditto	6.3
Removable ditto	2.17
Grs. of oxygen, &c., per 1000 grs.	.000125
Ammonia	present
Phosphoric acid	traces
Nitrous acid	present
Nitric acid, grs. per gallon ..	about 17
Total solids	80.5
Volatile matters	20.51
Mineral matters	59.99
Earthy salts and insoluble ..	36.05
Lime calculated as carb. ..	25.34
Silica	trace
Soluble salts	23.94
Chloride of sodium	13.44
Sulphate of soda	6.29 (23.54)
Carbonate of soda	3.81

"The surface of the water in the well regularly littered with dirt. No care seems to be taken to keep the well even in a decent state."

Notwithstanding the terribly bad state of the well, as given in the remarks, the amount of oxygen by the permanganate is a minimum. But the remarkable points, analytically, are the vast amount of volatile matters, and the non-appearance of any of the nitric acid amongst the regulation "soluble" salts. There is also a slight want of coincidence between the hardness, 8.47* (it was evidently

* The crows and ants consume everything eatable that is cast away; other refuse (and there is but little that crows and ants will not eat) is dried up by the sun.

taken very accurately), and the 36.05 grains of calcium and magnesium carbonate. I think that this specimen, out of hundreds, justifies my using the term "skittles" as the only qualification that can be applied to Dr. Macnamara's system of water analysis.

One word more. Dr. Macnamara says: "If I were now instructed by Government to do over again the work lately done in Bengal, I should feel much inclined to put into the hands of the analysts Messrs. Wanklyn and Chapman's work on "Water Analysis," &c. This is no doubt very flattering to the gentlemen named; unfortunately, Dr. Macnamara had the very opportunity he mentions within three months of the date of his letter. At about that time, the officers who perform the ungrateful duties of water analysts in India received each, not a copy of Messrs. Wanklyn and Chapman's treatise and some apparatus to work it with, but a copy of Dr. Macnamara's own new scheme, consisting of a patchwork of forty-six processes acknowledgedly picked out of books and put together without even being tried. In this scheme, like the first, there is not a trace of practical acquaintance with Indian waters.

ON THE TESTING OF MILK.*

By J. ALFRED WANKLYN,

Corresponding Member of the Royal Bavarian Academy of Sciences.

HAVING had occasion to examine a large number of specimens of milk during the past year, I have made some observations on the subject which possibly may not be deemed to be unworthy of the attention of those chemists who may have a like task before them.

The two common forms of malpractice which occur in the milk trade are—the practice of removing the cream from the milk, and the practice of diluting the milk with water; and the testing of milk resolves itself into the detection of skimming and watering, and the measurement of the extent to which these operations have been carried.

The possibility of detecting whether or not a specimen of milk has undergone impoverishment depends obviously on the possibility of assigning a normal composition to milk, or, at any rate, on the possibility of fixing limits beyond which the composition of milk does not vary.

From the observations of Alexander Müller and Eisenstuck, who carried out an investigation for the Royal Agricultural Society of Sweden, it appears that the milk yielded by a herd of cows remains very constant in composition throughout the year. A daily analysis of the milk given by fifteen cows, of different breeds, but uniformly well fed, exhibited the percentage of solids in the milk as never once during the entire year having fallen so low as 11.5. The highest percentage of solids was 14.08. Only four times during the year did the solids fall below 12 per cent. The average was 12.8 per cent.

My own observations, made on an entirely different plan, fully bear out the statement that cows' milk does not fall so low as 11.5 per cent of solids, and seldom so low as 12 per cent.

The following analyses may be published:—

Date.	Description.	Percentages.		
		Cream.	Solids dry at 100° C.	Ash.
I. 17 Feb., 1871	D. R.	10	12.24	0.76
II. 18 Feb., "	D. R.	—	12.04	0.68
III. 21 Feb., "	Cambridgeshire.	16	12.28	—
IV. " "	Surrey.	11	12.22	—
V. " "	Herts.	11	13.08	—
VI. " "	Essex.	11	11.80	—
VII. " "	Essex.	—	14.34	—
VIII. March, "	Country Milk.	9.8	12.45	0.71
IX. " "	Town-fed Milk.	13.0	14.07	0.74
X. April, "	Alderney Milk.	11.5	12.65	0.70

The first two specimens, named D. R., were specimens of milk bought from milk dealers believed to be perfectly

* Communicated by the Author.

honest. The next five specimens were samples of milk produced on farms in the different counties named in the table. Specimen VIII. is a sample taken by myself out of some 50 or 60 gallons of milk fresh from the country. Taken altogether, the ten analyses represent the composition of an immense quantity, and of a great variety, of milk, and support the conclusion arrived at in Sweden by Müller and Eisenstuck.

Before leaving the subject of the normal composition of milk, it is right to refer to the laborious investigation by Goppelsröder (*vide* "Verhandlungen der Naturforschenden Gesellschaft in Basel," 1866), which, at first sight, would seem to be in opposition to the above.

In reference to Goppelsröder's paper, the remark should first be made that that chemist does not appear to deny that the solid residue in the milk of a herd of cows keeps constantly above the level just indicated. The point which he insists upon is, that the milk of a single cow sometimes falls in richness below the normal level, and observations are cited in support of this statement. An examination of the results given in his paper does not lead me to a similar conclusion. In his paper I find many determinations of the solids in milk believed to be unsophisticated. Only four out of the entire number fall below 12 per cent. Now it is obvious that, however constant milk may happen to be as a matter of fact, it must always be possible, by a sufficient multiplication of analyses, to exhibit an analysis showing the sample of milk as having a composition outside the normal limit of variation. In other words, there is such a thing as error of experiment, and the question to be asked respecting Goppelsröder's four isolated cases of milk showing less than 12 per cent of solids, is, whether this divergence from the standard composition is real or only an error of observation. Two of these instances occur in Table I., at the beginning of the paper. Among eighteen samples of milk, yielded by a single cow in eighteen consecutive days, he finds one sample yielding 10.69 per cent of solids, and another yielding 11.41 per cent. In the same table Goppelsröder records the percentage of cream, and the specific gravity of the milk before and after skimming. It is remarkable that the two low percentages of solids are not accompanied by low yields of cream or low specific gravities. The former of the two (*viz.*, the 10.69 per cent of solids) is accompanied by 10 per cent of cream, *sp. gr.* 1.0316 before skimming, and *sp. gr.* 1.0332 after skimming; the latter (*viz.*, the 11.41 per cent of solids) by 11.2 per cent of cream, *sp. gr.* 1.032 before and *sp. gr.* 1.034 after skimming. The third instance of a too-low solid contents is to be met with in Table III., being the evening milk given by the last of eight cows. Percentage of solids, 11.43; cream, 7.5 per cent; *sp. gr.* before skimming, 1.0315; *sp. gr.* after skimming, 1.0335. In this instance the cream is indeed rather low, but then the effect of skimming on the specific gravity of the milk is considerable, and the specific gravity is high.

It is perfectly true that if a little cream be removed from rich milk, and a little water (I believe it should be warm) be added to the milk, the creamometer and "lactodensimeter" may be cheated, so that there shall be want of correspondence between the indications of these instruments and the solids in the milk. But in the examples at present under discussion we are not dealing with skillfully sophisticated milk, but with milk in the natural condition as given by the cow. If the figures in the tables be correct, the cow must have, in these three instances, given milk not only abnormally poor in solids, but also in an abnormal physical condition, as if it had been manipulated by the fraudulent milk-dealer.

The fourth case of abnormally low solids occurs in Table IV., being the milk of the third cow, which is recorded as containing 9.54 per cent of solids. In this instance, unfortunately, the yield of cream is not given. The *sp. gr.* before skimming was 1.0279, but the *sp. gr.* after skimming is not given. I observe, moreover, that the next solid contents of the table is a misprint, *viz.*,

3.7677 instead of 13.7677 (that it is a misprint is shown by the numbers for the ash and the number given as the ratio of the ash to the total solids).

I do not consider that Goppelsröder's four exceptional cases are sufficiently well established; and I consider it to be a well-established fact that the milk of a herd of cows in good condition always contains more than 11.5 per cent of solids, and that single cows almost invariably (if not always) yield milk containing more than 11.5 per cent of solids.

In dealing with milk supply on the large scale, we are little concerned with the possibility of single animals giving abnormal milk, and need only concern ourselves with milk of normal quality, all departures from the standard being looked upon as sophistications.

The following, which is the result of several concordant analyses of country-fed milk, may be taken as representing normal milk. In 100 grms. of milk:—

Solids (dry at 100° C.)	..	..	12.5 grms.
Water	..	..	87.5 "
			100.0

The 12.5 grms. consist of 9.3 grms. of "solids which are not fat," and of 3.2 grms. of fat.

If we consider the changes in composition which the addition of water to milk will produce, it will be apparent that it must diminish the proportion of solids in the milk, whilst the effect of skimming is to diminish the proportion of fat, and to leave the proportion of "solids not fat" unaltered (or indeed, strictly speaking, to make a very trifling increase in the proportion of the "solids not fat").

Treating the question quite rigidly, which I believe is the proper way of dealing with it, we arrive at the following:—

Problem I.—Given the percentage of "solids not fat" (=a), in a specimen of sophisticated milk (*i. e.*, milk either watered or skimmed, or both),—required the number of grammes of genuine milk which was employed to form 100 grms. of it.

Answer.—Multiply the percentage of "solids not fat" by 100, and divide by 9.3. Or—

$$\frac{100}{9.3} a.$$

Problem II.—Given the percentage of "solids not fat" (=a), also the percentage of fat (=b), in a specimen of sophisticated milk,—required the number of grammes of fat which have been removed by skimming from the genuine milk which was employed to form 100 grms. of it.

Answer.— $\frac{3.2}{9.3} a - b.$

In translating fat into cream, the rule is that a removal of 0.2 gm. of fat equals a removal of 1.0 gm. of cream. This rule is directly founded on experiment. I do not, however, claim a high degree of accuracy for the measurement of the cream.

Finally, a slight refinement may be noticed. If a specimen of sophisticated milk have been produced by both skimming and watering, it will be obvious, on consideration, that the extraneous water employed in manufacturing 100 grms. of it is equal to the difference between 100 and the quantity of genuine milk employed to make 100 grms. of sophisticated milk, together with a quantity of water equal to the fat removed by skimming.

$$\begin{aligned} \text{Extraneous water} &= 100 - \frac{100}{9.3} a + \frac{3.2}{9.3} a - b. \\ &= 100 - \frac{100 + 3.2}{9.3} a - b. \end{aligned}$$

An investigation of the different milks supplied to the different London Unions (which was made by me for the Government, at Mr. Rowsell's instance, last year, and which is published in Mr. Rowsell's "Report on the System of Supply of Provisions for the Workhouses of the Metropolis"), will furnish an illustration of this method of interpreting the results of milk-analysis.

In column 1 is given the designation of the sample, viz., the name of the Union which furnished it, and the number of the sample.

In column 2 is given the number of grms. of "solids not fat" contained by 100 grms. of the sample.

In column 3, the fat.

In column 4, the number of grms. of genuine milk which was employed in making the 100 grms. of sample (calculated).

In column 5, the number of grms. of fat removed by skimming from 100 grms. of sample (calculated).

In column 6, the number of grms. of cream which had been skimmed off 100 grms. of sample (calculated).

In column 7 is given the number of grms. of extra water which had been put into 100 grms. of sample (calculated).

Inasmuch as I have submitted the analyses of these warehouse milks to severe and elaborate treatment, it is right that some particulars should be recorded concerning the manner in which they were conducted. The ash of each milk was determined, and in no instance was it excessive in amount, showing that no mineral had been used to adulterate the milk. For organic adulteration I made no elaborate analysis; but no indication of such adulteration presented itself in the course of the examination: furthermore, I should add that I have never yet met with a case of adulteration of milk with organic substances, and believe it to be of very rare occurrence.

The solid residue dry at 100° C. was taken with great—and I believe unprecedented—accuracy. I have made a study of the taking of milk-residues, and set down the average experimental error in the solid residue as not more than 0.02 per cent. The solid residues were taken twice over, and the mean of the two closely-agreeing determinations was employed in the construction of the table.

The facts were taken with great care, but they do not pretend to so high a degree of accuracy as the total solids. It is hardly necessary to add that the numbers (designated as *a*) in the column headed "Grms. of Solids not Fat" were obtained by subtracting the quantity of fat (= *b*) from the quantity of total solids dry at 100° C.

The calculation of the quantities of genuine milk employed in making 100 grms. of the samples is based on the assumption, which I believe to be warranted, that milk is tolerably uniform in strength, consisting of 9.3 parts "solids not fat," 3.2 parts of fat, and 87.5 parts of water. This is the composition of country-fed milk. There is, however, an exceptionally rich milk given by highly stall-fed cows in town. This milk contains 10.0 parts of "solids not fat," 4.0 parts of fat, and 86.0 per cent of water; but it is comparatively rare.

If, in any instances in the above table, this rich stall-fed town milk have been employed instead of average country milk, then the real amount of watering and skimming in those instances is a little higher than the table exhibits. In the table there are seven examples of more than 100 grms. of genuine milk being used in making 100 grms. of the sample. Of these one appears to be an example of this town-fed milk, the rest not being sufficiently above 100 to call for such a supposition. The example to which I refer is the Shoreditch milk, which on the first occasion yielded 9.99 per cent of "solids not fat," which is a very close approximation to the "solids not fat" in 100 parts of town-fed milk.

When *a* exceeds 100 a minus-quantity will correspond to it in column 7, unless the slight correction for fat obliterate the minus-quantity of water. On calculating for town-fed instead of for country-fed milk, the minus-quantities in column 7 will disappear in every instance. The calculation for town-fed milk instead of for country-fed milk, as in the table, is simple, viz., substitute 10.0 for 9.3 *a*; substitute 0.4 *a* for 3.2 *a*.

The occurrence of minus-quantities in the column headed "Fat Removed" requires a word of explanation.

These minus-quantities have a real and substantial meaning. They are the quantities of fat which have been the reverse of removed,—that is to say, which have been added to the milk. Whenever one of these minus-quantities occurs in the "Fat Removed" column, one of three things has happened:—either the minus-quantity is within the limits of experimental error, as is the case with three of them (viz., -0.06, -0.05, and -0.07), or the milk was town milk, or the milk had through imperfect mixing received an undue share of the cream. There are only four cases of the kind in the table, viz., -0.57, -0.28, -0.47, and -0.34.

ON A SIMPLE MODIFICATION OF MOHR'S BURETTE, TO ADAPT IT FOR ALL TEST-FLUIDS.

THOSE who are much in the practice of volumetric analysis with Mohr's burette must often have felt great annoyance at the necessity of changing the instrument when operating with certain tests such as permanganate and others which act chemically upon the caoutchouc connectors. The extreme simplicity of Mohr's, and the facility with which it can be used, renders it by far the most desirable instrument; and for this reason it has been attempted to obviate this defect by a glass stopcock, which, while adding considerably to the cost, is by no means satisfactory in use; remarks which equally apply to Binks's and Gay Lussac's forms of burette.

The difficulty has, however, just been overcome in a simple and thoroughly effective manner by Capt. Heriot, R.M., and Mr. R. Biggs, surgeon, of Bath; and we present our readers with a sketch and explanation of the arrangement adopted by these gentlemen.

A represents Mohr's burette, with the caoutchouc connector, pinch-cock, and delivery tube removed. B, a sound cork fitted with a bent glass tube, C, firmly fixed into the mouth of the burette. D, a piece of caoutchouc tube sufficiently long to reach the table, terminating in a small glass mouth-piece, F. The pinch-cock, E, is affixed to the tube D at any part most convenient to the hand of the operator.

The advantages claimed for this arrangement are as follows:—

(1). That one form of burette (and that the best, viz., Mohr's) is available for every test-fluid, as under no circumstances can it come in contact with anything but the glass tube.

(2). That however narrow, such burette can be readily filled without the admission of air bubbles, by simply immersing the lower end, G, in the test-fluid, opening the pinch-cock, and applying suction to the mouth-piece, F.

(3). The extreme ease with which the apparatus can be washed, without even removing it from the stand, it being only necessary to remove the pinch-cock, and produce a syphon by drawing a continuous stream of water through it.

(4). The readiness of application to existing burettes at nominal cost.

It may be well to mention that as by this arrangement the orifice G becomes the terminal dropping tube, it would be advisable in new instruments to constrict its diameter so as not to deliver too quickly; and also that

in cases where a narrow burette or pipette is used, the cork and glass tube may be dispensed with, and the india-rubber applied directly to its upper end.

DIFFUSION OF MERCURIAL VAPOUR.

By M. MERGET.

THE only labours whose object has been the diffusion of mercurial vapours are those of Faraday, which are already half a century old, and whose conclusions, never having been contested during this long period, are accepted as facts acquired by science. The illustrious English physicist is known to have used as a reagent a gold-leaf suspended over mercury, which would blanch by amalgamation, or preserve its colour according to the emission or non-emission of vapour. After two experiments, one positive, the other negative, and availing himself, moreover, of facts previously observed by Davy relative to the transmission of electricity in the barometric vacuum, he was led to form the two following conclusions:—

(1). That the phenomenon of vaporisation of mercury is not continuous, and that its production absolutely ceases below the limit of about 50° .

(2). That at temperatures above that limit, and for a portion of the thermometrical scale which is not indicated by him, the vapours emitted contrary to the general law of diffusion of elastic fluids form above the generating liquid a very thin layer of vapour, which at an ordinary temperature scarcely attains a few centimetres thickness.

These conclusions are, on one hand, in direct contradiction to empirical and theoretical formulæ; explaining the maximum tension of vapours of perfect liquids with regard to temperature, and which all tend to admit implicitly the theory of continuous evaporation; and, on the other hand, they are also at variance with the ideas which now obtain as to the composition and properties of elastic fluids.

Opinions at the present time are generally unanimous in regarding gases and vapours as composed of molecules which move with considerable rapidity; that rapidity as regards each, depending on its nature and its temperature. Vapours which, when once formed, possess all the general properties of gas, are explained to consist of a detachment of molecules from the mass of generating liquid, which escape from its open surface at an average rate of speed to a height which increases with their temperature, and whence, in falling, they acquire the same rapidity of descent.

Faraday's experiments do not appear to me so decisive either by number or exactitude, as to prevent all doubts as to their correctness; which might be aroused by their opposition to a theory so plausible as the dynamic theory of gases.

These doubts having led me to retrace them, my first care was to obtain a reagent more impressionable to mercurial vapours than leaf-gold. Several others can be substituted; and of these, the most sensitive are saline solutions of the precious metals.

When spread upon common paper, after the addition of hygroscopic substances which retard their desiccation, these solutions are reduced by mercurial vapour according to the laws of Richter. The reduced metal again covers the paper, and communicates to it tints which become darker and darker, ending definitely in black; but of various tones according to the nature of the metals, and clearly characteristic of each.

The most common salts of the precious metals, such as nitrate of silver, the soluble chlorides of gold, platinum, palladium, and iridium, are those which have the best effect in the preparation of sensitive paper; moreover, as the sensibility of nitrate of silver is increased by the presence of ammonia through the action of that base upon the nitrate of mercury formed, it was thought that to

render the nitrate of silver ammoniacal would be advantageous, and experience confirms the supposition. Ammoniacal nitrate of silver, with which a few traces are drawn with a pen upon common paper, is the best reagent; but since paper impregnated with it becomes slightly tinged in the light, and also changes in the dark, although slowly, its employment must be dispensed with in long experiments, or in those made by too bright a light, such as that of the direct solar ray. In such cases, substitution may be made of the chlorides of palladium and platinum, which are almost unalterable either photo-chemically or spontaneously. By employing according to circumstances one or other of these three reagent papers, I have established the following facts:—

(1). That the vaporisation of mercury is a continuous phenomenon, which is not interrupted even by the solidification of the metal.

(2). That the vapours emitted possess a considerable diffusive power, which, without being exactly measurable, does not apparently differ widely from the amount assigned to it, *a priori*, by the deductions of the dynamic theory of gases.

The second of these conclusions arises from experiments made in very large and lofty spaces, where I found, from the floor to the ceiling, mercurial vapour emitted from very feeble evaporating surfaces of that metal. The first is the result of numerous experiments made at all temperatures included between $+25^{\circ}$ and -26° C., and of four experiments made at the temperatures of -30° , -35° , -40° , -44° .

I may draw attention to a last point of resemblance between mercurial vapours and the other elastic fluids, namely, the property which they possess of being condensed by a certain number of bodies absolutely devoid of all chemical action upon them, such as carbon, platinum; and of penetrating with extreme facility such porous substances as wood, unglazed porcelain, &c. From the preceding facts, numerous deductions may be drawn, of which I shall indicate only the principal. I establish first, in the domain of chemical analysis, the increase of exactitude and sensibility given to the process of qualitative examination of mercury, by the employment of ammoniacal nitrate of silver. It is known that in those experiments where the wet process is employed, the formation of an amalgam determined by simple precipitation upon a sheet of copper, or electro-chemical precipitation upon a sheet of gold, the amalgam being recognised first by its white colour; and, secondly, by the disappearance of that colour when it is heated. If, however, the liquids to be tested do not contain a sufficiently considerable quantity of mercury, the changes produced are of too undecided a character to be of any service. In these cases where no trace of amalgamation is discernible by the eye, whatever test may be employed, it is only necessary to apply the sheet of copper or gold to ammoniacal nitrate of silver paper in order to obtain a brown colour characteristic of the presence of mercury. In this manner I was enabled to establish the presence of mercury in solutions of the bichloride of FeCl_2 .

In experiments by the dry process, the mercurial vapours set at liberty were deposited upon the cold parts of the apparatus, where it was endeavoured to collect them into drops visible to the naked eye, or to the microscope; but this is not practicable if too small a quantity of mercury be employed. The slightest traces of vapour totally insufficient to yield a perceptible deposit, are, however, clearly shown by paper sensitised with salts of silver.

Reciprocally, the salts of precious metals are distinguished from all others by the effects of colouration, which result from their exposure to mercurial vapours; the shades of the darker tints which they then assume being to a certain extent characteristic of the kind of metal. Salts of platinum and of iridium, on account of the unalterability of the constituent metals, may be used to trace with pen or brush, not only on paper, but also on

the surfaces of all bodies incapable of chemically modifying them, characters or designs which, after reduction by mercurial vapours, are incapable of attack by almost all chemical agents.

The employment of these salts, together with mercurial vapour, is therefore an easy process for manufacturing indelible inks, suitable for writing or drawing on paper, linen, wood, &c. When formed with salts of gold, palladium, and silver, these inks, though less unalterable, may be used with advantage in particular cases.

Instead of using the solutions of these different salts as writing or drawing inks, they may be spread in thin layers upon common paper, and then exposed to the vapours emitted by drawings or characters previously mercurised. By thus reversing the question, I succeeded in resolving under new conditions, the problem of photographic impressions without light.

To do this it is only necessary to obtain a positive on glass, or even on paper suitably prepared with mercurial vapours, which are powerfully condensed by silver, and which it abandons when the plate is pressed upon a sheet of paper sensitised with a solution of one of the salts of the precious metals.

The proofs thus printed, when arising from a silver salt, are cleared and fixed by the usual photographic processes. When formed by salts of gold, palladium, platinum, or iridium, the clearing is naturally suppressed, and the fixing is obtained merely by washing in pure water. The proofs, after this unique and simple manipulation, are absolutely unalterable by light and all atmospheric agency. Moreover, those formed by reduced platinum or iridium are indelible, and cannot be destroyed except by such agents as will at the same time produce great changes in the substance of the paper upon which they are printed.

Substitution might advantageously be made for glass plates of metal sheets prepared for engraving, either by the application of photo-chemical processes, or by the graver, previously mercurising those portions of the sheet where the metal has been laid bare.

The permeability of porous bodies by mercurial vapour, allowed of my obtaining on sensitised paper impressions of leaves and plants; not only reproducing with irreproachable fidelity the finest details of the model, but causing them to stand out vigorously, by strong effects of contrast. When drawn from choice models, these impressions would make interesting collections of specimens for botanical lectures; and the process by which they were obtained might certainly be utilised in researches into vegetable anatomy and physiology. In animal physiology the study of questions relating to the effect of mercurials upon animal economy might be facilitated by the use of reagents which reveal the smallest traces of poisonous or medicinal agents, thus enabling their effects and mode of action to be more exactly studied.

A series of experiments made upon animals of small size, establish that mercurial vapours inhaled by them in open air are mortal in their effects. I therefore have commenced the study of this subject, which naturally bears much upon the health of those occupations into which the employment of mercury enters.

With regard to this subject, I will give an account up to the present time, of the general results of some observations made in a large workshop for silvering glass, occupying a large space, well ventilated, and all the appointments of which are perfectly appropriate for the carrying on of such an occupation.

In spite of the exceptionally advantageous hygienic conditions of these premises, I found that in the large apartment in which the mirrors received their coating, the atmosphere was at all times saturated with mercurial vapour from the floor to the ceiling; and that, although the workmen were in it only four hours a day, their skins, hair, beards, and all parts of their clothes were so strongly impregnated with condensed mercury, that even when not in the workshop, they were subject to the deleterious

emanations of that metal. A means of relieving them from this perpetual salivation is indicated in my memoir. —*Comptes Rendus.*

PROCEEDINGS OF SOCIETIES.

THE SCIENTIFIC AND MECHANICAL SOCIETY, MANCHESTER.

SECTION I.—ENGINEERING.

THE fifth monthly meeting of the session of the above Society was held on Wednesday, the 2nd inst., at the Trevelyan Hotel, the Vice-President in the chair.

The following gentlemen were elected Members of the Society:—Messrs. R. L. Mestayer, C.E., C. J. Allport, M.E., Frank Spence, Peter Spence, John Gilchrist, Peter Hart, Ivan Levinstein, James Nalder French, Chemical Manufacturers; Theodore Grosse, Charles Waring, C. S. Allatt, Alexander McKenzie, Mechanical Engineers; E. A. Axon, Nathaniel Cartwright, and A. Esilman.

By the unanimous vote of those present, a member was expelled from the Society, in consequence of not having put in an appearance at the last meeting, when the duty devolved upon him of reading a paper. The Secretary received no reply to his communications to him, and the last was returned through the Dead-Letter Office.

The Hon. Secretary then reported that the Special Committee, which had been elected at the last meeting to devise some improvement and reorganisation scheme for the Society, had held four sittings, at the first of which it was decided that no decisive steps be taken until a sufficient number of efficient, experienced, and influential gentlemen, representing the Sections to be at present organised, were added to the Committee. Deputations were consequently appointed to wait upon gentlemen in the engineering and chemical profession, who succeeded to add Messrs. Mestayer, C.E., Allport, M.E., Frank Spence, John Gilchrist, I. Levinstein, P. Hart, and J. N. French (chemical manufacturers) as members to the Committee. At a subsequent sitting, it was resolved that Sections be formed—at least one additional, viz., Chemical Section; also, that a Reference Library, Reading-Room, and Museum be established, and that the meetings be so arranged that all Sections meet on different days, so that each member might attend any meeting he pleased. It was hoped that other Sections would be formed in due course. The next business of the Special Committee would now be to construct as efficient a code of regulations as could possibly be done, and that was at present under consideration; and at the next Monthly Meeting, which was also the General Half-Yearly Meeting, the Committee would be prepared to lay a complete arrangement before the Society for approval. The Committee thought it also desirable that the Society should be known under a more suitable name in future; but, as the utmost importance was attached to this consideration, no resolution had as yet been come to.

The Chairman then called upon Mr. HACKING to read his paper "*On the Ventilation of Mines.*" He said there were now about 33,000 coal mines in the United Kingdom, from which the enormous quantity of 120,000,000 tons of coal were raised annually. The depths at which these black treasures, constituting such an all-important ingredient in the wealth of this country, were stored varies very much, the deepest workings in this country being the Dakinfield and the Rosebridge collieries, near Wigan, which latter had a depth of 2418 feet, and the average temperature was about 95° F. The danger attending the getting of coal was very great; this was partly due to the peculiar position in which the miner was placed, and partly to the terrible agencies reigning at these depths. A great difficulty was to obtain an efficient supply of pure

air, for which mechanical means had almost invariably to be adopted. A very common mode of ventilation was by means of one, two, or three shafts; at or near the bottom of one, the upcast, a fire was kept, which rarefied the air above, in consequence of which new air rushed in from the downcast, which had to make its way through the workings, and lastly to the fire.

The life of those employed in the pits was much endangered by what was called "fire-damp," which was light carburetted hydrogen (C_2H_4) mixed in certain proportions with oxygen, or, what is the same, atmospheric air. The gas itself, which issued from the pores and crevices of the coal, was inexplosive, but if atmospheric air contained more than 7½ per cent, and less than 13 per cent, the results were most terrible; if that mixture came in contact with a naked flame it would then explode. The supply of pure air was therefore required to be very ample, in order to keep the mixture below the explosive point. As a rise in the barometer indicated a decrease in the pressure of the atmosphere, a larger quantity of the gas would always be liberated when such a rise took place, and he suggested registering-barometers, which might be made to actuate an alarm as a safeguard.

Mr. HACKING was just alluding to the use of fans for ventilation, when the time arrived at which it was arranged the subject should drop, and be continued at a meeting in the ensuing session.

Mr. LYNDE then introduced the discussion on Sir William Fairbairn's new patent high-pressure boiler, which he illustrated by a good photograph and sketches on the black board, confining his remarks, however, to structural arrangements only. The boiler—which is intended to carry much higher pressures (about 150 lbs. on the square inch), as has hitherto been attempted in the Lancashire and Cornish boilers—is already tolerably well known to scientific readers, illustrations and descriptions having appeared in "The Engineer" (April 19th) and other journals. It is essentially what is technically known under "French boiler," "Woelf boiler," "Elephant boiler," or "Bouilleur boiler," with this material difference, however, that each of the two bottom tubes have internal flues containing the fire-grates, the same as a Lancashire boiler. These flues, which form an annular water-space through the whole length, are so arranged that for the purpose of cleaning, by loosening a few bolts, they may be withdrawn from the tubes, which latter are about 3 feet in diameter, communicating with one another. The entire circular shell constitutes heating surface.

Numerous questions were asked with regard to constructive detail, relative value of evaporating surface, &c., but the object of the discussion being merely to ventilate the opinion and probable experience of the members, but few questions could be satisfied, no paper having been prepared for the purpose. Various advantages and drawbacks were pointed out, but no defined decision was come to.

Votes of thanks to Mr. Hacking, Mr. Lynde, and the Chairman, terminated the proceedings.

CORRESPONDENCE.

NEW PROCESS FOR ANALYSING COMPOUND ETHERS.

To the Editor of the Chemical News.

SIR,—I think all chemists will agree with me that the publication of nearly 100 analyses, made according to a certain process, including several special control analyses showing the accuracy of the process, is something more than a mere "abstract statement that compound ethers admit of having the alcohol which they yield to alkalis measured or weighed."

The successful application to quantitative analysis of

the above well-known reaction was, I believe, new in 1867; it certainly was not new in 1872.

I hope Prof. Wanklyn will not be offended if I express a belief that I have induced at least one chemist to use my process; and as we all know how ably and perseveringly this chemist brings forward any method once adopted by him, I live in the pleasing hope that my process will soon be used by chemists generally, and, at any rate, am quite contented to let the matter rest here.—I am, &c.,

A. DUPRE, PH.D.

MISCELLANEOUS.

Food Adulterations Act.—The Vestry of Lambeth, at its meeting on Thursday, October 10th, appointed Dr. Muter, F.C.S., to be the Public Analyst for the Borough.

New Works by Professor Galloway.—Professor Galloway, of the Royal College of Science, Dublin, has two works nearly ready for the press. The title of one will be—"How the Natural Sciences are Taught, and how they ought to be Taught; with a Scheme for rendering more efficient the Government Science Schools." The title of the other will be—"A Manual of Applied Analysis."

Dublin Exhibition.—The Executive of the Exhibition Palace have determined upon introducing popular lectures, of a sound educational character, into their programme. They have been inaugurated by Prof. Cameron, the City Analyst, who is now delivering a series of twelve lectures on "Sanitary Science." We have no doubt that, in the hands of that talented Professor, they will prove a success, more particularly as they are being well illustrated by experiments. They are delivered twice a week, on Mondays and Fridays, in the large Concert Hall. As illustrating the character of these lectures, we will give the Syllabus of the fourth lecture, delivered on Monday, the 14th inst.:—Atmospheric Dust; Organisms in the Air; The Germ Theory of Disease; The Question of Spontaneous Generation, considered in Relation to the Origin of Zymotic Diseases.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 7, 1872.

This number contains the following original papers and memoirs relating to chemistry:—

New Experiments Made for the Purpose of Proving that the Yeast Germ which Induces Fermentation in Grape-Juice is Derived from the Outer Skin of the Grapes.—L. Pasteur.—In this memoir the author states that oxygen alone does not excite alcoholic fermentation in saccharine liquids. The reading of this paper at the meeting of the Academy gave rise to an animated debate.

Generation of Ferments.—E. Fremy.—Replied to by MM. Dumas and Pasteur.

New Facts Relating to the Theory of Fermentation Properly so-called.—L. Pasteur.—Reserved for full translation with the observations made by M. Fremy.

Researches on Crystalline Dissociation; Alums.—P. A. Favre and C. A. Vialon.—The continuation of a monograph on this subject, elucidated by several tables exhibiting results of experiments.

Efficacy of Lightning-Conductors.—W. de Fonvielle.—A report of the author's researches on this subject, and his journey to England for the purpose of learning what experience had been gained here respecting the efficacy of lightning-rods in protecting buildings against injury from electric discharges.

Action of Borax in the Phenomena of Fermentation.—M. Béchamp.—This paper records the results of a series of experiments made to show the effect of a concentrated (at 18°) solution of borax upon yeast and upon zymase (water obtained from the washing of yeast) when in contact with a sugar solution. First series—I. Sugar-water (1 of sugar to 6 of water), 5 c.c.; yeast-water, 10 c.c.; after fifteen minutes reduction of the cupro-potassic reagent. II. Sugar-water, 5 c.c.; yeast-water, 10 c.c.; distilled water, 10 c.c.; reduction after fifteen minutes, but less strong than in I. III. Sugar-water, 5 c.c.; yeast-water, 10 c.c.; borax solution, 10 c.c.; no reduction after twenty-four hours, but evident reduction after thirty-six hours. IV. Sugar-water, 5 c.c.; yeast-water, 10 c.c.; borax solution, 20 c.c.; no reduction after forty-eight hours. From this and two other series of similar experiments, the last being made with boric acid instead of borax, the author comes to the conclusion that the boric acid is not the cause of the peculiar action of borax on the fermentation; while he has found that the action of bicarbonate of soda is in a manner similar to that of borax. It is incidentally observed that the addition of one drop of creosote to 100 c.c. of fermenting liquid impedes neither the fermentation nor the intervention of the sugar.

Determination of the Vegetable Substances Present in Potable and in Insalubrious Waters.—E. Monier.—This paper contains the record of the results of a series of experiments made with various kinds of previously-filtered water, titrated at a temperature of from 85° to 90° with a solution of permanganate of potassa, in order to oxidise the organic matter present in a given quantity of water, or, in other terms, to decompose a certain quantity of the permanganate. 1 litre of the water of the river Dhuy decomposes 0.5 mg.; 1 litre (unit) of the water of the Seine, at Bercy, 4.5 mg.; same river, at the Pont Royal (Paris), 5.7; at Clichy, near Asnières (sewer), 11.0 to 18.0; at Saint Ouen, 7.6; at Saint Germain, 7.4; at Poissy, 5.1.

La Revue Scientifique de la France et de l'Etranger,
October 5, 1872.

This number contains no original papers relating to chemistry, but we call attention to the proceedings of the Sections for physics, astronomy, geodesy, mechanics, anthropology, and engineering, of the late Bordeaux meeting of the French Association for the Advancement of Sciences.

The First Century of the Belgian Academy.—F. Papillon.—From this paper we quote the following dates of foundation of scientific societies in Europe:—Rome, 1603; Del Cimento, Firenze (Florence), 1651; L'Académie des Curieux de la Nature, 1652; at Schweinfurt, by Dr. Bausch; Royal Society, London, 1665, as a private meeting; Royal Charter, 1660; Paris, 1666; Berlin, 1741; Bruxelles, 1792.

October 12, 1872.

This number contains no original papers relating to chemistry, but we notice the following:—

Scientific Journey to Bordeaux.—E. Alglave.—Under this title valuable and interesting information is given concerning the wine-production, industry, and commerce of the district.

Annales des Mines, No. 3, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Changes which the Sulphurous Waters of Eaux-Bonnes (Département des Basses Pyrénées, France) Undergo when in Contact with a Limited Quantity of Air.—L. Martin.—The contents of this memoir may be summarised as follows:—The sulphurous water of Eaux-Bonnes (a hot spring; temperature, 31°) when admitted into reservoirs, and left there in contact with a limited supply of air, exhibits two successive reactions:—the first is the rapid conversion of monosulphuret of sodium into bisulphuret, with formation of an equivalent of silicate of soda; the second is the gradual conversion of the bisulphuret of sodium into hyposulphite of soda, by fixation of oxygen. The water in the reservoirs contains constantly all the sulphur in the condition of bisulphuret of sodium and hyposulphite of soda; no sulphuretted hydrogen is given off, nor are any higher sulphurets formed. The water contains exactly 2 equivs. of silica to 1 equiv. of sulphuret of sodium; and the above-mentioned silicate, formed by the alteration of the water when in contact with air, is a quadri-silicate. The water is conveyed to the reservoirs from some distance, and is used for bathing purposes; it contains the total quantity of sulphur present in the original water, but in the state of monosulphuret of sodium mixed with hyposulphite of soda.

Palaeontological Essay on the Lower Oolite of the Limits of Southern and South-Western Central Plateau.—Dr. Bleicher.

Note on some Minerals from Chill.—E. Bertrand.—The author describes the following minerals:—Bordosite, so named from the locality in which it is found, consists of chloride of silver, and chloride and oxide of mercury; in 100 parts—AgCl, 31.23; Hg₂Cl, 45.53; HgO, 22.70. An arseniuret of copper, which is malleable and whitish-yellow coloured, contains 7.5 per cent of arsenic. Jalpaite, a sulphuret of silver and copper; in 100 parts—S, 14.02; Ag, 71.63; Cu, 13.06; Fe, 0.37.

New Silicate of Lime.—A. Piquet.—The mineral alluded to occurs at Sierra de Carija, in Spain, at a distance of 8 kilometres N. of Merida, in a quarry from which phosphate of lime is obtained. The

per cental composition of this mineral is as follows:—Lime, 46.410; magnesia, 1.301; alumina, with a trace of oxide of iron, 1.561; silica, 48.336; sulphuric acid, 0.562; carbonic acid, 1.000; water, 1.111; potassa, trace. The sp. gr. of this mineral is 2.799; its formula is 2SiO₃.3CaO.

Separation of Iron from Manganese.—J. P. de Rezende.—Reserved for full translation.

Annalen der Physik und Chemie, von Dr. J. C. Poggendorff, No. 9, 1872.
